ORIGINAL ARTICLES.

A CASE OF TUMOR OF THE SPINAL CORD.

BY GEORGE WOOLSEY, M.D.;

OF NEW YORK.

SURGEON, BELLEVUE HOSPITAL; ASSOCIATE SURGEON, PRESBYTERIAN HOSPITAL; PROFESSOR OF ANATOMY AND CLINICAL SURGERY, CORNELL UNIVERSITY MEDICAL COLLEGE.

CASES of spinal-cord tumor diagnosed, localized and operated upon are of sufficient interest to justify the report of the following case of tumor in the cervical region, successfully diagnosed, localized, and operated upon:

Mrs. S., aged thirty-four years, was referred to me for operation by Dr. Joseph Fraenkel, of this city, to whom I am indebted for the following history as well as for the accurate diagnosis and localization: In September, 1901, a fall into a ditch caused a bruise of the left hip and ankle. On October 23, 1901, she noticed that jolting in the cars caused pain in the left shoulder, at first dull and not very severe. This increased in severity and extended to the other shoulder, with pain in the back of the neck joining the two painful areas. It became shooting, and extended to the chest in knife-like radiations. In November, 1902, weakness of the left upper extremity was noticed in piano-playing, and simultaneously a band-like sensation was felt around the upper abdomen, most marked when she wanted to get up. Soon afterward there was weakness of the left lower extremity. Later, sensation on the right side was impaired. Sphincteric difficulties, not amounting to actual incontinence, have been present for the past month.

On examination in the latter part of January, 1903, the following points were noted: (1) Pain across shoulders and back of neck, slight all the time, worse in the morning and when sitting up without support. No severe shooting pains for the past month. (2) A girdle sensation across the upper abdomen, getting worse. (3) Tingling in hands, like electricity, more marked in left. (4) Difficult motion of the left upper and lower extremities. (5) She is most comfortable lying on the left side; contractions are worse on the right side. (6) Left fingers and toes straighten out and draw up painfully when she tries to sit up.

Furthermore, there is atrophic and flaccid paralysis of the left upper extremity, most marked in the triceps and extensors; spastic paralysis of the left lower extremity, with exaggerated knee-jerk and the presence of ankle clonus and Babinski phenomenon; and a spasmodic stretching of left hand and foot on change of posture.

As to the sensory symptoms, there is paresthesia of the right toes and dissociated sensory disturbances of the right side up to about the fifth thoracic vertebra. At this height and at about the sixth cervical vertebra there is a small band of hyperesthesia. The pain is worse at night. There is sweating of the face, especially at night. There is some tenderness, especially on left lateral pressure, over the fourth thoracic vertebra. The movement of the head backward gives pain in the back of the neck. The deep sensibility is lost in the left upper extremity.

On February 1, 1903, it was observed that the sensation of the left upper extremity (ulnar side) was not very acute, that the temperature sense was disturbed on both sides of the trunk, and that the muscles of the left hand reacted sluggishly to faradic stimulation.

The diagnosis of a tumor within the vertebral canal was made. There was some difference of opinion among those who had seen the patient as to its relation to the cord and membranes. It was thought probable by most that it was extradural, though an intramedullary situation had been suggested by one neurologist. The tumor was localized at the sixth cervical segment.

She was admitted to the Presbyterian Hospital on February 1, 1903, in the condition described above, except that with the progress of the paralysis she was even more helpless, and could not walk, stand, or raise herself up.

Operation.—Cervical laminectomy was done on February 2, under ether anesthesia, with the patient in a prone Sim's position. Median incision from 1½ inch below the external occipital protuberance to the first thoracic spine, deepened to spines of vertebræ, from which and the laminæ the deep tissues and periosteum were reflected by the elevator and knife. The hemorrhage was but moderate and easily controlled by pressure and hot-salt solution on one side, while the opposite side was being reflected. The spines of the fourth to seventh (inclusive) cervical vertebræ were removed by bone-cutting forceps, and the corresponding laminæ by the rongeur, piecemeal. Nothing appeared outside the dura, hence the latter was incised in the median line. The troublesome flow of cerebrospinal fluid from the cranial side of the opening was checked by inserting a small strip of gauze between the dura and the cord. The probe encountered no resistance except on the left side and anteriorly in the region of the sixth cervical lamina. Here the cord bulged backward considerably, and on pressing it to the right a dark bluish prominent area was seen on the left side, extending anteriorly. As this lay in front of the posterior nerve-roots, two of the latter overlying it were cut central to the root ganglia to get at the tumor. The latter was easily distinguished from the cord by its darker

color and harder consistence, and appeared to be covered by a capsule continuous with the pia, which was incised along the curved line where the tumor and the cord adjoined. The tumor, which was also adherent to the inner surface of the dura, was then fairly easily removed entire by blunt dissection, chiefly by the finger. It measured 2 cm. in length, 1¾ cm. in width, and 1¼ cm. in thickness, and was opposite the sixth cervical lamina, overlapping that of the seventh. The dura was sutured with fine gut and the deep parts were brought together by interrupted sutures of heavy gut, a small cigarette drain being introduced at the lower angle as far as the dura.

The patient continued in excellent condition throughout the operation, but on coming out of ether the paralysis was more marked than before, especially on the left side, and for some time after the operation she complained of paresthesia, especially prickling, which was most troublesome in the upper extremities. Profuse perspiration of the head was also very annoying.

The wound healed *per primam,* and it was two weeks or more before any marked improvement was noticed. This consisted in the return of motion, first in the right and then in the left leg. The left arm improved but slightly and slowly. For the first two weeks there was more or less incontinence. When she left for home, six weeks after the operation, sensation was about as before, except that the girdle sensation was not present. Considerable improvement occurred in motion. There was spasticity of both lower extremities.

A month later she was sitting up, could get out of a chair without assistance and walked with a spastic, paretic gait. Considerable paresis of the triceps and the extensors and flexors of the left wrist remained. There was loss of deep sensibility and of the stereognostic sense in the left hand. The paresthesia was but slight. Four months after the operation she walked without assistance with a spastic gait. Disturbances of sensation were less marked. Seven months after the operation the motion in the left upper extremity had also improved considerably. She has continued to improve still further.

Dr. Ewing pronounced the tumor to be an endothelioma.

This case in point of locality, in the cervical region, belongs to the rarest class of spinal-cord tumors. In the series of operated cases collected by Starr, Bruns, Putnam, and others, only one was located in the cervical region. Three such cases have been more recently reported by Oppenheim and Sonnenburg,[1] Henschen and Lennander,[2] Putnam, Krauss and Park.[3] In the above series also the operations on extradural tumors have far outnumbered those on intradural ones, although in fourteen cases recently reported the intradural have far outnumbered the extradural. The former most often allow of an exact diagnosis, and hence a good result from an operation. Hahn,[4] in 1902, reported the ratio of intradural to extradural tumors to be two to one.

In this report it is unnecessary to fully discuss the question of diagnosis, which depends upon a regular and oftentimes slow development that shows itself in an orderly sequence of symptoms due to pressure. The tumors are, as a rule, situated laterally, or laterally and posteriorly, and the pressure is usually first shown in the posterior nerve-roots as vague and then localized neuralgic pains, at first on one side, then on both, finally giving place to diminished sensation when the nerve-roots are destroyed. The symptoms of pressure on the cord itself may not occur until after a long interval (several years), and consist of (1) motor weakness beginning below the extending upward, at first on the side of the tumor, paraplegia only developing later. Then (2) diminution of sensation of all kinds but in different degrees occurs, advancing from below upward and being most pronounced on the side opposite the tumor. Thus Brown-Séquard's paralysis is not infrequently observed in these cases. At the upper border of the hypesthesia there is hyperesthesia in a small circular zone or in spots.

The question of segment diagnosis is of the greatest importance and interest, for on this depends the resort to operative removal. The upper limit of the tumor is the most important to locate, as it has been a common experience since Horsley's first case to find the tumor higher than it was diagnosed. To determine this limit, and the segment or segments involved by the pressure, we have both the motor and sensory symptoms. The sensory are more important than the motor symptoms for this purpose, and those of sensory paralysis (anesthesia, etc.) than those of sensory irritation. In this connection it is important to observe that, according to Sherrington's experiments, each nerve-root is intimately connected with those above and below, and, owing to this and the numerous anastomoses between the nerve-trunks, no one muscle or area of skin is supplied by a single root or segment, but in addition by the segment or root above and below, so that the tumor may be placed two segments higher than the symptoms. Hence Bruns says the operation should be done two segments above the upper level of pain, and, according to Starr, the cord should be exposed four inches higher than the level of the spinal nerve in which the pain is found. Furthermore, the afferent and efferent tracts run in the substance of the cord for some distance, possibly the distance of two segments, before they reach the nerve-center in the gray matter. This fact may further increase the ease of mistakes in locating a tumor lower than it really is.

Jaffe,[5] in reporting an autopsied case, found that the tumor was in the spinal segment which governed the upper limit of the area of diminished sensation or the transition from the diminished to the normal sensation, supplied by the anastomoses of the intact roots above.

Schede,[6] in reporting four cases operated upon, states that the upper end of the tumor was regu-

larly found in the segment which represented the upper border of the disturbance of sensation.

The diagnosis of the nature of the tumor is more difficult than its position. Sarcomata are the most common variety, forming forty-five per cent. according to Bruns's statistics, forty-two per cent. according to Putnam's and Warren's. Extradural growths are more apt to be malignant than intradural. Those progressing rapidly are probably malignant. But in the case of any tumor within the spinal cord, as within the cranial cavity, the prognosis is necessarily fatal if the tumor is left to itself.

Laminectomy in itself is not a very serious operation, and according to McCosh the operative mortality should not be over ten per cent. The fact that resort to operation has generally been delayed too long, until the cord is seriously compromised, bed-sores or cystitis have developed, and the general condition has greatly deteriorated, is responsible for the high mortality. Bruns gives thirty per cent. of recoveries, Krause 56.3 per cent., and in the last twelve cases operated on seventy-five per cent. The prognosis is worse the higher the tumor is situated. Spinal tumors are more often removable than cerebral ones. According to Starr,[7] out of 122 cases the operation should have been feasible in 76, and from pathological reports the tumor could have been removed in seventy-five per cent. Thus these tumors are far more accessible than cerebral tumors.

In considering the *operative treatment* it is well to repeat the statement of Starr and McCosh, that although compression from a tumor of the cord may exist for a long time without softening, no delay should be made for antisyphilitic treatment, for gummata of the cord are rare and the results of delay may be most unfavorable.

As it is, strictly speaking, impossible to assign a certain lesion to a definite segment, but only to an area within three segments, hence, given the highest segment of the cord opposite which the tumor may be situated, we expose this by removing the neural arches of not less than three vertebræ, and any slight inaccuracy of localization may be counterbalanced by the length of the area of the cord exposed. At least this much has to be exposed for the proper manipulations in the removal of the tumor. For operative purposes the surgeon must know the relations of the segments to the vertebræ and really to the spines of the vertebræ, for these are our only superficial landmarks, and in the cervical region even these fail us. These relations of the cord segments to the vertebral spines are given in various tables with a fair degree of accuracy, though if the considerations already given do not suffice to explain the frequency of the tumor being found higher than located, some inaccuracy in these tables or even an individual difference may account for it.

As to the technic, even in the deep wound in the cervical region hemorrhage was not serious and was easily controlled. It is a matter of individual preference what one uses for the removal of the laminæ. Cutting forceps for the spines and rongeur forceps for the laminæ I have found effective. Schede recommends the Gigli saw in the cervical region to divide the laminæ. Uhtoff's osteoplastic resection is to be condemned. It prolongs and complicates the operation, and the laminæ and spines do not serve to carry any of the weight. Hence no support is necessary after the operation.

Sonnenberg[1] has reported one case of a tumor in the cervical region of the cord in which he attributed the fatal result to the use of this method of temporary resection.

The flow of cerebrospinal fluid may be a great inconvenience in the removal of the tumor. In my case, a little sterile gauze inserted behind the cord between it and the dura at the upper or cephalic end of the incision checked this flow very satisfactorily. For the same purpose Schede has used the circular constriction of the dural sac above and below the incision by a silk or elastic ligature, as proposed by Sick.

The tumor is usually readily shelled out by blunt dissection. In the above case two posterior nerve-roots had to be divided to get at it.

The improvement, as in the case reported, may not commence until two weeks or more after the operation. It appears first and is most complete on the side where the symptoms last appeared. The symptoms continue to improve for a considerable time, but some permanent effects of the pressure may persist from destruction of the cord on the side of the tumor, depending on the size of the tumor and the length of time it has exerted pressure. For this reason alone it cannot be too strongly urged that suitable cases of tumor of the spinal cord be operated upon as soon as it is possible to localize them.

THE NEED OF EFFICIENT PUBLIC HEALTH WORK IN THE SUBURBS.[1]

BY GEORGE A. SOPER, PH.D.,
OF NEW YORK.

Before attempting to form an idea of the need of public health work in the suburban districts of New York it may be well to picture to ourselves the principal types of suburbs, and agree upon some of the leading features of suburban life which make a strict surveillance of public health there desirable.

The word "suburban" carries to some minds a pleasing picture of quiet country homes in pretty villages within easy reach of the city. The streets are smoothly paved, and shaded in summer, and there are lawns about the houses which give an

1 Abstract of a paper read before the Municipal Club of Brooklyn, N. Y.

air of ease and order to the place. Many of the dwellings are admirably built for the admission of light and air and relatively high standards of hygiene prevail within them. There are about forty towns and villages of this kind within a half hour's journey of Manhattan.

Notwithstanding the orderly and agreeable appearance of many of the environs of this type, the machinery for guarding public health in them is not always highly developed. The members of the boards of health usually serve without pay. The boards are often made up of men not one of whom has had any training in public health work.

It is for this reason that many suburban towns are not provided with as perfect sanitary arrangements as they should have. Water supplies and sewerage systems are occasionally defective. It is unusual to find the milk supplies well regulated. Disinfection and isolation for the prevention of contagious diseases rarely receives scientific attention. Hospital accommodations adequate to the needs of the population are seldom provided. The most important detail of all public health work, the registration of cases of infectious diseases, births, marriages and deaths, is often so much neglected that it is impossible to tell from the records whether the community is enjoying its proper share of health.

In some suburbs an attempt is made to attend to public health work in a modern way, but the annual reports of the majority show that there is much halfheartedness and lack of skill in the effort. The suburbs in which thoroughly competent public health work is performed are conspicuously few.

Yet a wise and competent administration of public health matters is much needed in residence suburbs. Many are, in reality, health resorts. People live in them for the rest and healthfulness which they are supposed to afford.

If there was no other reason why a strict surveillance of public health were required the fact that most of these residence communities are growing rapidly would afford one. It is as true with respect to communities as it is with individuals, that the period of growth and adolescence is a period of unusual danger to health. Our residence villages and towns are always outgrowing their sanitary arrangements. For example, the sewer which was big enough for a population of five thousand a dozen years ago is inadequate for seven thousand who need to use it to-day.

To some the word suburb does not call to mind an attractive picture. It is remembered that between the beautiful residence suburbs and the city lies a district which is anything but pleasant: where the built-up sections end and the country farms begin. It is a region largely given over to what are called by public health authorities the "offensive trades," and the city on the other hand, and the country on the other, seem bent upon making it as offensive as possible. Here are slaughter houses, oil yards, fertilizer plants, chemical works and dumping places for the miscellaneous filth of the city.

The location of offensive trades in the suburbs is a relic of the times when civilization knew little about sanitary science. In those days the pollution of the atmosphere with foul odors was considered inevitable. To-day we know that these odors may be largely prevented and that it is often business economy to do so.

Such dwellings as exist on the outskirts of the city are the homes of poor people. The houses consist of meanly-built frame structures, packed on small lots and surrounded by barren wastes. Public works for the development of the city have left sunken lots on every hand. Some of the depressions are filled with green, slimy water. Here mosquitoes breed and carry malaria.

Life, as seen at the edges of the city, is often as squalid as anything to be found in the most overcrowded tenements. In fact, existence here is sometimes less healthful than life in the giant tenements in town. The dwellers in the tenements have at least the benefits of a public water supply, a sewerage system and some share of board of health control, while the people on the outskirts of the city are apt to be left to shift for themselves. Inside, the houses are often filthy, unventilated and overcrowded. Outside, the back yards contain all the sanitary conveniences which the people think they need. Here is a well and a privy; here are thrown ashes and garbage and house slops. Chickens, goats, etc., are the scavengers.

Between the immediate squalid outskirts and the pleasing residence suburbs of the city lies a large tract of country which is being gradually transformed. The city has extended its streets and avenues partly through these districts, but sewers and water works are not yet built and board of health work is unknown. The progress of municipal improvements has not been an unqualified advantage. On every hand the natural drainage of the land has been interfered with. Acres of sunken lots are to be seen and acres of stagnant water. Years must pass before these lands are reclaimed by their owners. Meanwhile the region is fairly certain to gain an evil reputation for malaria. Malaria is indeed a common disease of most suburbs.

A favorite occupation in this class of suburb is the business of keping cows for milk. In the vicinity of New York are many so-called dairies filled with cows which are imprisoned in their stables the year round. Few people who see in our city or suburban streets immaculately painted milk wagons bearing such legends as "Sweet Clover Farm" or "Brookside Dairy," for instance, have any idea of the filth and squalor from which many of these wagons draw their supplies. How many people take the trouble to learn where their milk comes from, and what pains are taken to keep it pure?

Having made a brief survey of some of the conditions which render strict attention to public

health matters desirable in the suburbs, we are in a position to group under a few general heads the difficulties in the way of protecting health and point out the remedy.

First in importance among the difficulties I should place the want of knowledge which everywhere exists on the subject of hygiene. In the better residence suburbs we have seen that public sanitary questions are often neglected. In the squalid outskirts of the city private and domestic hygiene are practically unknown. Hygiene is a neglected factor in education, as has been pointed out by President Eliot, of Harvard. Children, as a rule, do not study it at school, and in later life seldom acquire any knowledge of it beyond that gained by costly observation and experience.

Nor are our doctors always qualified to act as expert advisers with respect to public health measures. Few physicians have studied hygiene and fewer yet of forty years of age or more could have studied its foundation science, bacteriology, in their college courses, for it has not so long been taught.

Second in importance as an obstacle to protecting public health, I should place the difficulty of enforcing sanitary laws. If the suburb is not a part of the city the authority of the health board is apt to be inadequately understood by the board itself, as well as by the public. The authority of the health board is in reality very great. No more power is given by the statutes to any department of local government than is conferred upon boards of health for the proper discharge of their duties.

Thirdly, a want of concerted action among different departments of the local government accounts for some of the difficulties in the way of protecting public health in the suburbs. There is not infrequently a tendency for each bureau to pursue its labors without regard to the activities of the rest, and this often leads to difficulty. For example, it is incongruous for a department of health to declare that the private dumping of garbage or swill is a nuisance, if at the same time city scavengers are permitted to tip their refuse in sunken lots.

A remedy is available for the difficulties of caring for public health in the suburbs. Be they aristocratic villages or mere squalid outposts of the city, energy is needed to discover and correct the sanitary conditions. Get all the help possible!

Health authorities are often embarrassed by the small number of paid employees under their direction, but they generally receive an important amount of assistance which is not paid for. All physicians are called upon by law to supply information concerning sickness, deaths and births for the information of the health department. In a similar way ministers are required to report marriages. Citizens who are annoyed by unsanitary conditions in their neighborhood, commonly lodge complaints.

Extend this cooperation. Let the character and amount of the assistance be increased; let the personnel of the boards of health be improved; let the appropriations for the maintenance of the boards be adequate; establish laboratories to test water and milk; inspect the dairies and the water shed. Above all, engage a competent health officer to execute the orders of the board.

See to it that the suburb is healthful and that the public has the reasons for knowing it to be so. Publish a monthly report and state the facts with regard to the prevalence of preventable diseases, if they are prevalent.

A policy of indifference or a disposition to hide the facts may be fatal. It has often led to a great epidemic.

As soon as possible, see to it that that universal nuisance, the garbage question, is solved in a sane and sanitary manner. As certainly as garbage and ashes must be disposed of there is an orderly and inoffensive way to dispose of them. There is absolutely no warrant for polluting the air and making a suburb or any part thereof a disgusting dumping place for refuse.

Begin to collect a library on sanitary topics. Whether you are a member of the board of health or not, it is important that you should know when and where cases of transmissible sickness are likely to occur, how infectious diseases may be communicated and how they may be prevented. It is desirable that the principles of disinfection, isolation, bacterial cleanliness and domestic hygiene should be generally known and applied. The members of the board of health ought to be experts in these matters.

Efficient work on the part of the board of health will be certain to bring a rich reward. Life and health will be more secure. The suburb will be cleaner morally. Higher standards of municipal order will prevail. Not the least reward will be the business advantage which will come from the prosecution of a strict and skilful public health campaign. Intelligent people will be attracted to the suburb. From a purely mercenary standpoint health work pays.

A CONTRIBUTION TO CYTODIAGNOSIS IN PLEURAL EFFUSIONS, WITH ESPECIAL REFERENCE TO THE TUBERCULOUS FORM.

BY HERBERT SWIFT CARTER, M.D.,
OF NEW YORK.

Cytodiagnosis of pleural effusions is a subject which, until very recently, has been entirely ignored, although the cells of the blood, and those found in exudates from some other portions of the body, have long been studied and discussed. The extreme importance, to the patient, of a positive diagnosis in suspected tuberculosis anywhere, can scarcely be overestimated, and, as a rule, the earlier diagnosis the more favorable the result; hence, when a patient with a pleural effusion is presented, a practically positive diagnosis of its etiology, *i.e.*, whether tuberculous or

not, offers the best chance for the individual's proper care.

To emphasize this the more, according to Cabot[1] fifteen per cent. of 152 cases of pleurisy with effusion developed demonstrable tuberculosis of lung or bone, in three per cent. of which the tuberculosis manifested itself within two years of the date of the effusion. Since he used no positive method for determining which were tuberculous and which were non-tuberculous, undoubtedly a considerable number of the latter were included among the observations, so that, proportionately, the number of cases which developed tuberculosis would probably be considerably greater had the non-tuberculous cases been positively excluded from the series.

Widal and Ravant[2] were the first to call attention to a lymphocytosis in the so-called idiopathic pleurisies, but their conclusions, so far as the establishment of a positive diagnosis of their tuberculous origin, are incomplete, as they took into account only the differential cell count, while as a matter of fact a more complete morphological examination of the effusion is necessary; and there are other diagnostic points, without which one cannot make a diagnosis of tuberculous pleurisy, especially the *specific gravity*, *fibrin*, and *albumin content*, all of which are of extreme importance. There are many cases in which the lymphocytes predominate, although they are in nowise tuberculous, as shown by Series D.

Reasoning also by analogy, Hand[3] found that he was able to demonstrate tubercle bacilli in the spinal fluid from cases of tuberculous meningitis, in practically every case. In these he also found a lymphocytosis, but in addition an albumin content as high as nine per cent., whereas the normal spinal fluid contains but about five-tenths per cent. and that of the ordinary meningitis four to five per cent.

The fluid from two cases of proven tuberculous peritonitis was also examined and showed a lymphocytosis, one of 98.6 per cent., another of ninety-nine per cent., each with high fibrin and albumin percentages.

Runeberg[4] long ago demonstrated the great difference in the albumin content of exudates and transudates, the latter having but a small percentage as compared with the former; while it is a matter of common experience that the specific gravity of exudates exceeds that of transudates, so that one can almost positively state that a pleural fluid with a specific gravity over 1010 or 1012 is exudative, while that below is the result of transudation. Hence it is only by a combination of morphological data that we are able to arrive at a practically positive diagnosis of tuberculous pleurisy, without animal inoculations, and that this can be done with what seems reasonable certainty, is the object of these observations.

Animal injections are, above all, too slow, and much valuable time is lost to the patient in waiting for results, three weeks being about the shortest time in which tubercles may be demonstrated, and then not with certainty, while guinea-pigs survive injections of tuberculous pleural fluid two or three months, when one often finds the tubercles well developed and cheesy. Taken in connection with the difficulties of the process and the failures, it is too uncertain to ever become generally useful, while a morphological examination can be easily and rapidly made and the results, for the various forms of pleural effusion, are nearly uniformly constant.

The advantage, too, of differentiating *statim* the exudates due to tubercle bacilli and pneumococci by this morphological examination is evident, for the majority of cases of each begin in much the same way, chill, pain in the side, and a high temperature, often 103° to 104° F., and when one has to go entirely by the history it is often quite impossible to say whether the patient has had an initial pneumonia with subsequent fluid, or whether it has been acute tuberculous pleurisy from the start, *e.g.*, Series B, Case XIV. Many samples of fluid came marked with a clinical diagnosis which proved on further examination to be wrong.

By reference to the tabulated cases one can see that only three of the positively tuberculous, and two of the probably tuberculous cases were at all subject to rheumatism, and it is to be doubted if the rheumatic poison ever gives a true pleural effusion, although this is a time-honored theory, and there is nothing theoretically against such a possibility, Dopter[5] going so far as to describe the characteristics of rheumatic pleurisy; but Wolf[6] says that what were previously described as such are now known to be tuberculous, in all probability; and certainly this series of cases seems to bear out that statement most emphatically.

True cases of septic pleurisies (empyemata) are of no interest from a cytodiagnostic point of view, for, like all pus, the polymorphonuclears predominate almost to the exclusion of all other forms, and the etiological diagnosis can, so far as we know, be made only by cultures.

Method of Morphological Examination of Pleural Fluids.

Fluids should be examined as promptly after aspiration as possible, immediately after, while still warm, and before the fibrin clot forms, if animal inoculations are to be made; for judging from Hand's experience with spinal fluids, the tubercle bacilli, or their spores, are entangled in the fibrin, as he was able to find bacilli, in his cases, only in it and never in the fluid, no matter how treated. The color, turbidity, specific gravity, reaction, and relative albumin content are then obtained. The latter is quickly done by adding strong nitric acid, when a large amount of albumin comes down in the form of thick, curdy clots; a small amount either as a light flocculent precipitate or a simple turbidity. When the fluid cools, the presence or absence of a fibrin clot is noted. This is a gelatinous mass when seen

fresh and undisturbed, but on agitation of the fluid collects into a small opaque mass of more dense fibrin resembling that seen after whipping fresh blood.

The amount of fluid used successfully in inoculating guinea-pigs varied from 2 to 9 c.c., and the injection was made subcutaneously into the anterior chest-wall, under conditions as nearly aseptic as practicable.

To complete the examination, a conical tubeful of the fluid is then rapidly centrifuged for five minutes and the sediment stained on a coverslip with Jenner's differential stain. A differential count is then made of the leucocytes; the endothelial cells, erythrocytes and general characters noted. In no instance were tubercle bacilli found in the fluid, although about one-half of the cases were examined for them. All the pleural fluids were either alkaline or neutral reaction, usually strong alkaline.*

Series A.

Observations on cases of pleuritic effusion of proven tuberculous origin.

Case I.—Tapped twice. Thirty-two ounces. Highest temperature, 104° F.; average, 102° F. Fluid. Specific gravity, 1024. Fibrin, moderately large amount.

Lymphocytosis on differential count:

	Per Cent.
Small lymphocytes	92
Large mononuclears	7.2
Polymorphonuclears	.8
Eosinophiles	.0
	100.0

Result of guinea-pig inoculation: General tuberculosis in spleen, liver, lungs, glands. Tubercle bacilli in abundance.

Case II.—Tapped once. Thirty ounces. Highest temperature, 104.5° F.; average, 101.2° F. Fluid. Moderately large amount of fibrin.

Lymphocytosis on differential count:

	Per Cent.
Small lymphocytes	98
Large mononuclears	2
Polymorphonuclears	0
Eosinophiles	0
	100

Result of guinea-pig inoculation: Tubercles in spleen, liver, axillary and peritoneal glands; cheesy, tubercle bacilli in abundance.

Case III.—Tapped twice. Twenty-three ounces. Highest temperature, 105.5° F.; average, 101.5° F. Fluid. Specific gravity, 1012. Fibrin, moderately large amount. Albumin, large amount.

Lymphocytosis on differential count:

	Per Cent.
Small lymphocytes	90
Large mononuclears	1.7
Polymorphonuclears	7.7
Eosinophiles	.3
Basophiles	.3
	100.0

Result of autopsy: Acute miliary tuberculosis of both lungs, tubercular peritonitis.

Case IV.—Tapped twice. Sixty ounces. Highest temperature, 101° F.; average, 99.5° F. Fluid. Specific gravity, 1019. Fibrin, large amount. Albumin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	100

Result of autopsy: Both pleuræ thickened; fresh tubercles on left pleura; old tuberculous foci with cicatrization on right.

Case V.—Tapped once. Twenty-five ounces. Highest temperature, 104° F.; average, 101° F. Fluid. Specific gravity, 1014. Fibrin, large amount. Albumin, large amount.

Lymphocytosis on differential count:

	Per Cent.
Small lymphocytes	98
Large mononuclears	2
	100

Result of guinea-pig inoculation: Scattered miliary tubercles throughout both lungs and spleen; cheesy axillary glands.

Result of autopsy on patient: Miliary tubercles over both pleuræ and in both lungs; tuberculous peritonitis and colitis.

Case VI.—Tapped once. Forty-eight ounces. Highest temperature, 100.5° F.; average, 98.4° F. Fluid. Specific gravity, 1022. Fibrin, moderate amount. Albumin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	97.5
Large mononuclears	2.5
	100.0

Result of autopsy: Miliary tubercles on right pleura and scattered throughout the right lung. Had articular rheumatism five years ago.

Case VII.—Tapped twice. Forty-five ounces. Fluid. Specific gravity, 1022. Fibrin, large amount. Albumin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	98.4
Large mononuclears	.3
Polymorphonuclears	1.3
	100.0

Result of autopsy: Miliary tubercles on right pleura and in right lung; extreme arteriosclerosis with cardiac hypertrophy and dilatation; chronic myocarditis; chronic diffuse nephritis.

* It will be seen in looking over the cases that sometimes there is no mention of the specific gravity or the fibrin or the albumin content. This is owing to the fact that in some of the earlier cases their importance was not recognized and the results were originally to be based on subsequent histories of the cases after two to five years, so that sometimes only a differential count was made. The later cases wre all routinely examined as detailed above.

Case VIII.—Tapped once. Twenty-five ounces. Highest temperature, 102° F.; average, 100.4° F. Fluid. Specific gravity, 1022. Fibrin, large amount. Albumin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	96
Large mononuclears	1
Polymorphonuclears	3
	100

Result of guinea-pig inoculation showed tuberculosis of lungs.

Case IX.—Tapped once. Forty ounces. Highest temperature, 104° F.; average, 101.5° F. Fluid. Specific gravity, 1012. Fibrin, large amount. Albumin, large amount.

Lymphocytosis, on differential count:

Small lymphocytes	100
Large mononuclears	0
	100

Result of autopsy: Fluid in both pleural sacs; acute miliary tuberculosis, both lungs; chronic endocarditis, with marked cardiac hypertrophy and dilatation. Had articular rheumatism two years ago.

Case X.—Tapped three times. Forty-three ounces. Highest temperature, 104° F.; average, 101.1° F. Fluid. Fibrin and albumin in large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	100

Result of guinea-pig inoculation: Miliary tuberculosis of lungs and liver.

In looking over this series one is struck by the following facts: That so far as examined, they show a fluid with a specific gravity over 1012, ranging from 1012 to 1024, with an average of 1018.3, a large or moderately large fibrin clot, and a large amount of albumin, besides a lymphocytosis from ninety to one hundred per cent., averaging 96.9 per cent. (Here and elsewhere a lymphocytosis refers to the small lymphocytes.)

The day of disease on which these cases were tapped varied from the fifth to the forty-second as follows: Fifth, sixth, seventh, thirteenth, fourteenth, sixteenth, twenty-first, twenty-eighth, thirty-seventh, and forty-second, but not even in those examined during the first week was there seen a polymorphonuclear leucocytosis, as is said often to be the case by Guilland,[7] Wolf,[6] Barjou and Cade[8] and Utichelis[9]. The nearest approach to this was seen in Case X, Series B. It would seem, however, from the observations of others that a high polymorphonuclear leucocytosis might be found early, and subsequent differential counts be necessary to clear the diagnosis, although comparatively few cases need tapping much before the latter part of the first week, unless the fluid accumulates very rapidly.

The relative number of cells in the fluid appears of no importance, or at least their importance, if any, is not known, for in this series some cases showed a very large number of cells, and in others it was necessary to count an entire coverslip in order to get fifty or a hundred for a diagnosis; this too, after centrifugating. A point of interest is, that, so far as noted, some of the cases showed the presence of few endothelial cells, and others of many, which is quite at variance with Dopter's[5] statement that "in tuberculous pleurisy, we find particularly an absence of endothelial cells." Nor are their presence a positive indication of an effusion of long duration, as they were found in abundance in Case XI on the sixth day.

The temperature curve in these cases of proven tuberculous pleurisy is also of interest compared with the probably tuberculous and postpneumonic cases, the highest temperature recorded being 105.5° F., while the average highest was 103.2° F. The average range from admission to discharge being 100.7° F. (see Table of Averages), hence it is seen that the true tuberculous cases show a tendency to high temperatures, particularly early in the disease, or until the fluid is at least in part removed.

The color of the fluids varied between a straw, amber, greenish, yellow or reddish tinge, the highest recorded amount of fluid obtained being forty-eight ounces, lowest twenty-three ounces, with an average of 32.6 ounces.

Two cases of especial value from the point of view of differential diagnosis, were numbers VII and IX.

Number VII was that of an old colored man with extreme arteriosclerosis, myocarditis and chronic nephritis, who from time to time had excessive attacks of contraction of the arteries, with asthma. He got up fluid in one side of his chest, and at first the natural supposition was that it was a transudate, as he had been gradually failing. However, a diagnosis of tuberculous pleurisy was made after a morphological examination of the fluid, as it showed the typical earmarks of a tuberculous effusion, and this was confirmed at autopsy, ten days later. Case IX was somewhat similar, although a marked endocarditis with failing compensation was the occasion for seeking hospital treatment. The mitral and aortic valves were much damaged, and the fluid which collected in both pleural sacs was supposed to be the result of his impared circulation. Examination of the fluid showed it to be a tuberculous process, this also being confirmed by autopsy.

Series B.

Observation on Cases of Pleuritic Effusion of Probable Tuberculous Origin.

Case I.—Tapped three times. Ninety-two ounces. Highest temperature, 102.4° F.; average, 100.8° F. Fluid fibrin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	98.8
Large mononuclears	.7
Polymorphonuclears	.5
	100.0

Tubercle bacilli found in sputum.

Case II.—Tapped twice. Nineteen ounces. Highest temperature (in hospital twenty-five days after onset), 101.8° F.; average, 100° F. Fluid fibrin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	98
Large mononuclears	2
	100

Case III.—Tapped twice. Thirty-four ounces. Highest temperature, 104.6° F.; average, 100.5° F. Fluid fibrin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	95
Large mononuclears	2
Polymorphonuclears	3
	100

Gave good reaction to tuberculin, 2 mgr.

Case IV.—Tapped twice. Fifty ounces. Highest temperature, 102.8° F.; average, 100° F. Fluid. Specific gravity, 1020. Fibrin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	98.3
Large mononuclears	.3
Polymorphonuclears	1.4
Eosinophiles	.0
	100.0

Râles at right apex. Severe hemoptysis. Had articular rheumatism fifteen years ago. Gave good reaction to tuberculin, 2 mgr.

Case V.—Tapped twice. Forty-two ounces. Highest temperature, 102.2°F.; average, 100° F. Fluid. Specific gravity, 1020. Fibrin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	98.6
Large mononuclears	1.2
Polymorphonuclears	.0
Eosinophiles	.2
	100.0

Gave good reaction to tuberculin, 2 mgr.

Case VI.—Tapped once. Eighteen ounces. Highest temperature, 103.8° F.; average, 100° F. Fluid. Specific gravity, 1020. Fibrin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	91.6
Large mononuclears	8.4
	100.0

Case VII.—Tapped four times. One hundred and fifty-two ounces. Highest temperature, 103.8° F.; average, 101.8° F. Fluid. Specific gravity, 1020. Fibrin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	96
Large mononuclears	2
Polymorphonuclears	2
	100

Case VIII.—Tapped three times. Fifty-six ounces. Highest temperature, 103.4° F.; average, 99.5° F. Fluid. Specific gravity, 1024. Fibrin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	100
Large mononuclears	0
	100

Case IX.—Tapped four times. One hundred and eighty-nine ounces. Highest temperature, 104.2° F.; average, 100.7° F. Fluid. Specific gravity, 1022. Fibrin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	100

Patient had bloody expectoration.

Case X.—Tapped twice. Fifty-three ounces. Highest temperature, 103.6° F.; average, 102° F. Fluid. Specific gravity, 1018. Fibrin, large amount.

Lymphocytosis, on differential count:

		Per Cent.
On the eleventh day.	Small lymphocytes	65.5
	Polymorphonuclears	34.5
		100.0

		Per Cent.
On the sixteenth day.	Small lymphocytes	97
	Polymorphonuclears	3
		100

Case XI.—Tapped once. About forty ounces. Highest temperature, 102° F.; average, 100° F. Fluid. Specific gravity, 1020. Fibrin and albumin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	100

Case XII.—Tapped once. Twenty-three ounces. Highest temperature, 103.5° F.; average, 100.7° F. Fluid. Specific gravity, 1.018. Fibrin and albumin in large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	98.00
Large mononuclears	1.33
Polymorphonuclears	.67
	100.00

Case XIII.—Tapped once. Fifty-two ounces. (Fluid in chest on discharge.) Highest temperature, 103°F.; average, 100.6° F. Fluid. Specific gravity, 1016. Fibrin and albumin in large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	100

Patient has night sweats.

Case XIV.—Tapped once. Ten ounces. Highest temperature, 103° F.; average, 99.5° F. Specific gravity, 1016. Fibrin and albumin in large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	94
Large mononuclears	0
Polymorphonuclears	6
	100

Sent to laboratory for diagnosis.

Case XV.—Tapped once. Six ounces. Highest temperature, 102.2° F.; average, 99.6° F. Fluid. Specific gravity, 1015. Fibrin, moderate amount; albumin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	84
Large mononuclears	3
Polymorphonuclears	10
Eosinophiles	0
Basophiles	3
	100

Gave good reaction to tuberculin, 4 mgr.

Case XVI.—Tapped twice. Eighty-nine ounces. Highest temperature, 104.5° F.; average, 101.5° F. Fluid. Specific gravity, 1016. Fibrin and albumin, large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	94.5
Large mononuclears	0.0
Polymorphonuclears	5.5
	100.0

Fine râles at right apex. Tubercle bacilli in sputum.

Case XVII.—Tapped once. Fifty-five ounces. Highest temperature, 102.5° F.; average, 100.2° F. Fluid. Specific gravity, 1024; albumin in large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	95.0
Large mononuclears	4.0
Basophiles	1.0
	100.0

Fine râles at both apices of lungs. Moderate reaction to tuberculin, 2 mgr.

Case XVIII.—Tapped three times. One hundred ounces. Highest temperature, 105° F.; average, 100° F. Fluid. Fibrin and albumin in large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	96.5
Large mononuclears	0.0
Polymorphonuclears	3.5
	100.0

Had articular rheumatism five years ago.

Case XIX.—Tapped twice. Sixty-two ounces. Highest temperature, 101.8° F.; average, 100.2° F. Fluid. Fibrin and albumin in large amount.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	91.5
Large mononuclears	5.0
Polymorphonuclears	3.5
	100.0

Fine crepitant râles at left apex persisting for months.

Case XX.—Tapped four times. One hundred and fifty-nine ounces. Temperature about normal. Fluid. Specific gravity, 1016. Fibrin and albumin in large amount, reddish color.

Lymphocytosis, on differential count:

	Per Cent.
Small lymphocytes	87.0
Large mononuclears	.5
Polymorphonuclears	12.5
	100.0

Although the patient had a chronic endocarditis, the effusion was probably a true exudation on account of its specific gravity, fibrin, and albumin content. Had articular rheumatism twenty years ago.

In the cases which are included among those of probable tuberculous origin, one sees the marked similarity to those of proven tuberculosis, in the specific gravity, albumin, and fibrin content and in that each has a lymphocytosis. While some of them have points in their physical examination of the lungs—sputum, tuberculin reaction—which stamp the effusion as almost surely of tuberculous origin, *e.g.* Cases I, IV, IX, XVI, XVII, the others are included in the series on account of their conforming more or less closely in the morphological examination of the fluid to those known to be tuberculous. (Series A.)

The specific gravity of these effusions, where noted, ranged from 1015 to 1024, with an average of 1019.4, as compared with 1018.3 of Series A, a very slight difference. The fibrin and albumin content, wherever noted, was large, as was the case also in Series A; while the small lymphocytes ran from 84 to 100 per cent., (omitting Case X, which showed 34.5 per cent. of polymorphonuclears on the eleventh day, while the small lymphocytes went up to 97 per cent. on the sixteenth day), with an average of 96.1 per cent. as compared with 96.9 per cent. of Series A.

The amount of fluid withdrawn was from 6 to 159 ounces, averaging 53.2 ounces, which is a somewhat higher quantity as compared with the cases of proved tuberculosis.

So far as temperature is concerned in these cases, we find it from 105° F. to normal, but with an average highest temperature of 102.9° F., as compared with 103.2° of Series A, the average temperature for all from admission to discharge being 100.4°, or almost exactly that of the tuberculous cases. (See Table of Comparisons.)

Following these comparisons it is easily seen that the diagnostic points of Series A and B are for the most part almost identical, and offer good ground for making a fairly positive diagnosis of tuberculous pleurisy in the cases of Series B. An odd fact is that in those cases in which the tuberculous pleurisy was not terminal, the patients were in almost every instance attacked while in apparently robust health, many, if not quite the majority of them, never having been ill before.

Series C.

Observations of serous pleuritic effusions following lobar pneumonia.

Case I.—Tapped once. Thirty ounces. Ten days after defervescence. Highest temperature, 100.5° F.; average, 99° F. Fluid, Fibrin, large amount, clear amber. Polymorphonuclears in excess.

	Per Cent.
Polymorphonuclears	58.6
Small lymphocytes	36.4
Large mononuclears	5.0
	100.0

Case II.—Tapped twice. Ten ounces. Highest temperature, 102° F.; average, 100° F. Fluid. Specific gravity, 1016. Albumin in large amount, straw amber. Polymorphonuclears in excess.

	Per Cent.
Polymorphonuclears	75.6
Small lymphocytes	23.4
Eosinophiles	1.0
	100.0

Tapped seven days after end of pneumonia; temperature continued moderately elevated.

Case III.—Tapped once. Five ounces. Highest temperature, 100.2° F.; average, 99.5° F. Fluid. Specific gravity, 1016. Fibrin and albumin in large amount. Polymorphonuclears in excess.

	Per Cent.
Polymorphonuclears	67.5
Small lymphocytes	28.5
Large mononuclears	4.0
	100.0

Tapped six days after defervescence; fluid looked like slightly diluted blood.

Case IV.—Tapped twice. Six ounces. Highest temperature, 105.2° F.; average, 103.2° F. Fluid. Specific gravity, 1015. Fibrin, rather curdy, albumin fairly heavy amount. Polymorphonuclears in excess.

	Per Cent.
Polymorphonuclears	92.5
Small lymphocytes	.5
Large mononuclears	7.0
	100.0

Fluid accumulated during course of long pneumonia.

Case V.—Fluid from operation unknown amount, bloody character. Highest temperature, 101.5° F.; average, 100.5° F. Fluid contained a fairly large blood clot. Polymorphonuclears in excess.

	Per Cent.
Polymorphonuclears	78.0
Small lymphocytes	11.5
Large mononuclears	10.5
	100.0

Operation performed supposing it an empyema; no morphological examination preceded. Microscopical examination showed diplococci which looked like pneumococci. No cultures made. Patient died. (Child.) No autopsy.

Case VI.—Tapped once. Thirty ounces. Highest temperature, 104° F.; average, 101.5° F. Fluid, green amber. Specific gravity, 1019. Fibrin and albumin in large amount. Polymorphonuclears in excess.

	Per Cent.
Polymorphonuclears	71.2
Small lymphocytes	28.8
Large mononuclears	0.0
	100.0

Tapped on the fourth day of pneumonia; signs of consolidation persisted after the fluid was withdrawn and defervescence came normally.

This series is given as illustrating the points in differential diagnosis from the tuberculous cases, which is accomplished principally by the differential cell count; as the color, specific gravity, albumin and fibrin content are much the same as one finds in the cases of tuberculous origin, either proven or probable. When the differential cell counts are examined and compared with the other classes one sees an invariable polymorphonuclear leucocytosis ranging from 58.6 per cent. to 92.5 per cent., with an average of 71.7 per cent., even though the serum is often clear and corresponds in other respects to the tuberculous effusion.

So far as the development of an empyema is concerned, no prognostic value could be attached to the percentage of polymorphonuclears, as none of these cases developed it.

In examining the temperature curves it is seen that when an effusion developed during the course of a pneumonia the temperature was that belonging to the original disease, and was high, as in Case IV and VI; leaving these out of account we have a highest temperature from 100.2° F. to 102° F., with an average highest temperature of 101.5° F., which is much lower than that of Series A and B (see table); while the average

for the entire series (again with the same two exceptions) is seen to be 99.7 per cent., which is also lower than that of either of the two preceding classes. While these cases are too few in number to formulate positive conclusions from, still, it seems pretty certain that cases of pneumonic serous effusion have a lower average temperature than tuberculous cases, although there are exceptions at both ends of the scale.

The amount of fluid withdrawn, while not positively of diagnostic value, is of interest by comparison. The amount varied from five to thirty ounces, with an average of 18.5 ounces, or much below that of the tuberculous cases.

Several samples of fluid were received with the diagnosis of tuberculous pleurisy, which had the characters of a postpneumonic effusion.

The interest in this class of cases is twofold: First as illustrating the differential points between a transudate and an exudate, the former having a low specific gravity average 1008.6 for these cases, a small amount of fibrin, or none at all, and a small amount of albumin, which appears simply as a cloudiness of the fluid or at most as a light, flocculent precipitate on adding strong nitric acid. Second, in that the transudates all show a *positive lymphocytosis*—eighty-six to one hundred per cent., showing the fallacy of what has already been said, of basing a diagnosis of tubercular pleurisy simply on the differential count, as has been done by Dopter,[6] while Guilland [7] lays stress on the presence of large numbers of endothelial cells as a diagnostic point in transudates, also fallacious, as shown by reference to Series A and B, where large numbers of endothelial cells were frequently seen.

OBSERVATIONS ON CASES OF PLEURAL TRANSUDATES.

Series D.—Transudates.

Diagnosis.	Color of Fluid.	Specific Gravity	Fibrin.	Albumin.	Differential Count.	Small Lymphocytes Per Cent.	Large Mononuclears. Per Cent.	Polymorphonuclears Per Cent.	Eosinophiles. Per Cent.	Basophiles. Per Cent.	Notes.

Transudates	1008.6	None or Small	Small	Lymphocytosis 95 per cent.	?	?	?

Among the various pleural fluids examined there were two cases resulting from pistol-shot wounds of the chest-walls which gave a marked eosinophilia—one of 70.2 per cent., the other 87.8 per cent. of eosinophiles. The significance of this is not known, and although Widal and Revant [2] report three cases somewhat similar, the eosinophiles running from fourteen to fifty-four per cent., they offer no explanation, and these cases are reported merely as curiosities.

CONCLUSIONS.

While, of course, these cases are too few in number to draw positive conclusions from, the results, as outlined, are at least extremely suggestive, and so far as one can see the uniformity of the analyses in the various series of cases, seems to justify the following tentative conclusions:

1. That a true pleural effusion has a specific gravity over 1010, usually much higher, with an average of about 1017.9; a high fibrin and albumin content.

2. A pleural transudate has a low specific gravity, with an average of about 1008; a small fibrin and albumin content.

3. An almost certain diagnosis of tuberculous pleurisy as can be made by the morphological examination of the fluid alone, and rests on its having a high specific gravity—1012 to 1024, average, 1018.6; a large amount of fibrin and albumin, with an accompanying lymphocytosis. There is usually a considerable rise of temperature at the outset, which may average 103.4° F.

4. According to some authorities, one may find a polymorphonuclear leucocytosis before the third or fourth day of a tuberculous pleurisy; in which case, subsequent examinations will be necessary to establish a positive diagnosis.

5. A diagnosis of postpneumonic serous effusion lies in its high specific gravity, averaging 1016.5; large fibrin and albumin content, with a polymorphonuclear leucocytosis, 58 to 92.5 per cent., averaging 71.7 per cent. The temperature is usually much lower than in the tuberculous cases, unless complicating an active pneumonia, averaging at the outset about 101° F.

6. A differential diagnosis between a pleural transudate and a tuberculous pleurisy cannot rest alone on a differential cell count, as they both show a lymphocytosis, but must rest on a more complete examination, including the specific gravity and the amount of fibrin and albumin, as already shown and explained.

AN ANALYSIS OF FORTY-TWO CASES OF VENOUS THROMBOSIS OCCURRING IN THE COURSE OF TYPHOID FEVER.

BY W. S. THAYER, M.D.,
OF BALTIMORE, MD.;
ASSOCIATE PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE, MD.

In connection with some studies in which we have recently been engaged concerning the cardiac and vascular complications and sequels of those cases of typhoid fever which have been observed in the last fourteen and a half years in Dr. Osler's wards at the Johns Hopkins Hospital, I have gathered together a few statistics with regard to the cases of venous thrombosis which are, it seems to me, of a certain interest.

Out of 1,463 cases of typhoid fever there have been 39 instances of venous thrombosis, a percentage of 2.6.

In addition to these, two similar cases were admitted during convalescence, while one man who had suffered from double iliac thrombosis coming on during typhoid fever, entered the hospital for treatment two years later.

Mortality.—In five of the 39 cases occurring in the hospital there was a fatal result—12.3 per cent. In two instances the thrombosis was the direct cause of death, once (No. 27,855) through a pulmonary embolism from a thrombus of the left axillary vein, and once (No. 28,600) from the dislodging of a piece of a thrombus in the left iliac vein with resulting embolism of the inferior cava and right auricle.

Distribution of the Lesions.—(*a*) *As to section of the body.* The seat of the thrombus was: In the lower extremities in 40 instances; in the upper extremity in one; in the pulmonary artery in one.

(*b*) *As to side of the body.* The occluded vessel was: On the left side in 26 cases; on the right side in five; on both sides in nine; imperfect records in two.

(*c*) *As to vessel affected.* The affected vessels were: The femoral vein in 21 instances; the popliteal vein in five; the iliac vein in five; the veins of the calf alone in five; the internal saphenous in three; the pulmonary artery alone in one; the pulmonary artery and common iliac in one; the axillary vein in one.

Time of Onset of the Symptoms.—In 39 cases developing in the hospital the time of onset was as follows:

Weeks.

1	2	3	4	5	6	7	8	9	10	11	12	13	14
1	1	10	9	5	3	2	4	0	1	1	0	1	1

Symptoms.—1. *Fever.*—In 36 of our 39 cases the development of the thrombosis was associated with fever. In three there was no fever. In 26 cases the fever was intercurrent, the thrombosis coming on before complete defervescence. In 13, the temperature was normal at the time of onset.

2. *Chills.*—In 11 or 28.2 per cent. of these 39 cases, the complication was associated with chills.

In two instances the chills occurred just at the time of recognition of the thrombosis. In two cases the chills occurred before recognition; once four days, and once a week before. In six cases the chills occurred during the complication; once during the period of subsidence and in the other five instances during the height of the process. Once the chills occurred before, during and after the onset of the thrombosis. In one of the three cases entering the hospital after the acute symptoms had passed, a history of chills during the course of the fever was obtained, though their relation in time to the development of the thrombosis was not clear.

3. *Pain.*—The first definite symptom of the thrombosis in every instance was pain. This varied considerably in intensity and suddenness of onset.

In all the cases of *femoral thrombosis* but one there was pain along the course of the femoral vein. In this instance the only symptoms noted in the hospital were those of popliteal thrombosis. The subsequent history of the case, however, made it clear that there must also have been plugging of the femoral vein.

The first localizing symptom of the process was: Pain along the course of the femoral vessels and in Scarpa's triangle in nine cases; pain in the calves in five; pain in the popliteal region in one; unsatisfactory note in three; patient too ill to localize pain in one.

In three of these cases the onset of the pain was strikingly sudden. In the five cases of *popliteal thrombosis* the first localizing symptom in every instance was pain in the popliteal region. In the five cases of *iliac thrombosis* the onset was associated with a sudden sharp abdominal pain in four instances. In one of these cases the pain was extremely severe and associated with leucocytosis. Perforation was suspected and exploratory laparotomy was performed. In the five cases of thrombosis of *deep veins* of the calf the first symptom in every instance, was pain in the calf.

In the three cases of thrombosis of the internal saphenous vein alone, the first symptom in every instance was pain along the vein.

4. *Edema.*—In all of the 39 cases there was swelling of the affected part. In most instances the temperature was raised, and in a number of cases there was redness over the affected vessel. A definite note as to the existence of edema was unfortunately not made in all instances.

(*a*) In 19 cases of femoral thrombosis edema was noted in 11 cases; "swelling" alone in six. There was no edema in two cases.

(*b*) In five cases of iliac thrombosis there was edema in two instances; no edema in three.

(*c*) In five cases of popliteal thrombosis there was edema in two instances; "swelling" in one; no note in one; no edema in one.

(*d*) In five instances in which the deep veins of the calf were apparently alone involved there was edema in one case; "swelling" in three; no edema in one.

(*e*) In all three cases in which the internal saphenous and veins of the calf were involved there was edema.

5. *Palpability of the Thrombotic Mass.*—In 16 out of the 39 cases the thrombotic mass was felt as a palpable cord.

6. *Leucocytosis.*—In 22 cases counts of the colorless corpuscles were made during the complication.

The leucocytes were over 20,000 in	3 cases.
15,000 to 20,000 in	3 cases.
10,000 to 15,000 in	6 cases.
9,000 to 10,000 in	3 cases.
8,000 to 9,000 in	1 case.
7,000 to 8,000 in	1 case.
6,000 to 7,000 in	2 cases.
2,000 to 3,000 in	1 case.

It will thus be seen that in 12 or 54.5 per cent. the leucocyte counts was above 10,000, while in 15 or 66.1 per cent. it was over 9,000.

The highest count, 24,864, occurred in a case of iliac thrombosis in the third week of typhoid fever. In this instance an exploratory laparotomy was performed in view of the possible existence of perforative peritonitis. The lowest count, 2,700, occurred on the day after the onset of a thrombosis, apparently of the popliteal, which occurred in the sixth week without fever and with very slight general symptoms. In eight instances only was a count made on the day of onset of the symptoms.

In these cases the leucocyte count was:

Above 20,000 in	2 cases.
Between 15,000 and 20,000 in	1 case.
Between 10,000 and 15,000 in	1 case.
Between 9,000 and 10,000 in	1 case.
Between 7,000 and 8,000 in	2 cases.
Between 6,000 and 7,000 in	1 case.

In connection with these blood counts it should be remembered that, in every instance but one, the phlebitis came on in the third week of the disease, or later, at a period when according to our statistics, the leucocyte count in uncomplicated cases should not be above 5,500.

Association with Secondary Infections.—Out of our 39 cases there were seven instances in which secondary infections had preceded or coexisted with the onset of the thrombosis.

These secondary processes were: Boils in two cases; well-marked bronchitis in one; gangrene of the lung in one; fistula in ano in one; chronic otitis media in one; amebic dysentery with developing hepatic abscess in one. In the remaining 32 instances there was no clinical evidence of secondary infection.

Post-Mortem Appearances.—In the three instances in which bits of clogged vein were examined histologically evidences of well marked inflammatory changes were found in the walls of the vessel—such, however, as might well have arisen secondarily to the thrombosis. In one of these cases there was, at the point of section, an extensive endophlebitic plaque which, however, probably dated from a period preceding the

typhoid fever. The sections examined came from a spot above the point of origin of the thrombus. There was nothing in the sections which would justify one in drawing conclusions as to the cause of the thrombosis or as to the pre-existence of a phlebitis.

Cultures.—In one case the *Bacillus typhosus* was obtained in pure culture from the thrombus. In one the cultures were negative. No notes were made with regard to cultures from the thrombus in the other two autopsied cases.

After-Results.—Sixteen patients were seen or communicated with at periods, months or years after the onset of the complication. Ten of these were cases of femoral thrombosis; two, of double iliac thrombosis; two, of popliteal thrombosis; two, of thrombosis of the deep veins of the calf.

(*a*) *After-History of Ten Cases of Femoral Thrombosis.*—One patient was seen 2½ months after convalescence; one, ten days after his discharge from the hospital, while two of the others were communicated with a year after the onset, by letter. The other six patients were examined at periods varying from two to twelve years after their illness.

In all instances there was more or less permanent disability. In six cases there had been *edema* lasting for from several weeks to two years. In five cases there was a complaint of *cramps* in calves, especially at night and after exercise. In one the patient complained of sharp *pains* running up through the leg and thigh, especially after standing. In one instance the patient said that when he uses his leg too much "it becomes so weak that he can hardly move it; it seems to give out." In every instance the affected leg and thigh were materially and permanently *larger* than the other. In all cases, excepting in the instance seen ten days after discharge, there were marked *varices*. These were especially extensive in the calf, the popliteal space and on the posterior and inner side of the thigh. In six cases, all but one in which the condition was looked for, there was well-marked varicosity of the veins in the hypogastrium. These seemed to be characteristic. The dilated veins form a triangle with the apex a little below the umbilicus, the blood flowing from the affected thigh to the apex of the triangle and then down again into the inguinal ring upon the other side, passing upward evidently through the opposite iliac vein.

(*b*) *After-History of Two Cases of Double Iliac Thrombosis.*—Two patients who had had a double iliac thrombosis were seen several years after the onset of the complication. In one of these instances there was at first much edema and persistent weakness of the legs. In the other there were few subjective symptoms. In both cases there were most extensive varicosities on both legs and thighs extending upward over the abdomen and anastomosing with the internal mammary veins and other veins in the axilla. The accompanying photograph shows the condition of the more marked of these two cases.

(*c*) *After-History of Two Cases of Popliteal Thrombosis.*—Two cases of popliteal thrombosis were seen several years after the onset of the complication. One of these patients had complained of no trouble whatever. In the other the leg was somewhat weak, and toward the end of the day, it became at times edematous. In both instances the affected leg was somewhat larger than the other, but in neither were there marked varicosities.

(*d*) *After-History of Two Cases of Thrombosis of the Veins of the Calf.*—In one case there was, after leaving the hospital, considerable edema

Fig. 1.

Abdominal Varices in a Case of Typhoid Thrombosis of both iliac veins.

with the development of several ulcers. There is now a fairly well-marked varicosity of the veins of the inner side of the leg and in the popliteal space. The other patient was communicated with by letter. He states "That the leg from the knee down is the source of a little continuous annoyance. It itches and is frequently inflamed during the warm months. It often goes to sleep." The calf measures an inch and a half more than the other.

Final Observations.—Conclusions based upon so small a series of observations are hardly justified. There are, however, one or two points worth emphasizing.

1. In 42 cases of typhoid thrombosis the onset occurred almost invariably in the third week or later.

2. Local pain and fever were usually the first

symptoms. The fever sometimes preceded the localizing symptoms.

3. In 28.2 per cent. of our venous thrombosis occurring in connection with typhoid fever there were chills. In several instances the chill preceded the appearance of localizing symptoms. In the past two years I have seen in consultation three further cases in which otherwise unaccountable chills during convalescence from typhoid fever, were followed by a complicating thrombosis.

4. Venous thrombosis in typhoid fever is usually associated with an increase in the number of leucocytes. The extent of the leucocytosis depends apparently in part, at least, upon the extent of the lesion. It may be moderate, but in other instances of considerable extent—over 20,000. In mild cases it may be absent.

5. The thrombosis is commonest in the lower extremities, especially on the left side. The femoral vein is involved with particular frequency.

6. In the event of a sudden severe pain in the lower part of the abdomen coming on during the latter part of typhoid fever and associated with a leucocytosis, the possibility of iliac thrombosis should always be considered.

7. Venous thrombosis in a lower extremity is always a serious complication of typhoid fever. Although the immediate danger is not great the after results are often grave. In thrombosis of the femoral or iliac veins the affected extremity is usually considerably and permanently enlarged and there is usually more or less permanent disability, extensive varices, often resulting in ulceration; marked weakness of the limb; frequent cramps in the muscles, especially at night and after overexertion. In thrombosis of the popliteal or deep veins of the calf alone, the permanent changes are much less severe, though the leg always remains larger than the other.

8. In thrombosis of the femoral vein a greater or less part of the blood from the affected extremity is often carried up by the iliac vein of the opposite side, the current crossing the abdomen through anastomosis in the hypogastrium, resulting in a characteristic triangular area of varicose veins.

THE TREATMENT OF SIMPLE RECTAL FISTULA BY EXCISION AND SUTURE WITHOUT CUTTING THE EXTERNAL SPHINCTER MUSCLE.[1]

BY HOWARD A. KELLY, M.D.,
OF BALTIMORE.

I am not aware exactly what plan of treatment for simple fistula is regarded as best by our proctologists to-day, but I desire to suggest for their consideration a method I have tried in about five cases, within the past ten years, with three successes.

To employ this treatment successfully the fistula must be simple and direct, as ascertained by exploring it with a probe, or, better still, by a careful palpation of the lower periphery of the bowel between the thumb and the index finger. I empty the bowel thoroughly, having the patient under my care for at least two days before the operation.

The rectum then is dilated under the anesthetic and a pack is inserted within the ampulla. The external orifice of the fistula, which must be free from any signs of surrounding infiltration, is then circumcised, and after being grasped with forceps the fistulous tract is carefully dissected out, up to its abutment on the mucous surface of the bowel, in the region of the internal sphincter muscle.

The rectal orifice is now very carefully excised through the wound, so as to make a transverse opening parallel to the sphincter fibers, when the excision is completed, and the fistula removed. If the wound is a shallow one, it may be closed by introducing a few interrupted silkworm-gut or silver wire sutures, extending from the skin surface down to the bottom, care being taken to draw the circular muscular fibers together above and below the rectal orifice. I have not yet tried it, but I believe that a figure of eight suture would serve a good purpose by avoiding the use of any buried sutures in a deeper wound. Buried sutures of fine catgut may be used at the bottom of the wound to bring the muscular tissues snugly together horizontally. In whatever way the suturing is done, the utmost care must be taken to bring the tissues everywhere into good apposition and to avoid leaving any dead spaces.

The margin of the bowel is next everted, and the operation concluded by closing the opening on the mucous surface with fine silk sutures. It is a good plan to cut away some of the mucosa below the rectal end of the fistula, so that when the mucous membrane is sutured the mucosa from the upper margin of the opening is drawn down and sutured to a point a centimeter or more below the orifice, in this way covering it in by withdrawing the line of suture from any direct relation to the deeper wound. Dr. J. M. T. Finney has brought the mucosa out into the skin surface and sutured it there with a good result.

After such an operation I make no effort to move the bowels for from five to seven days, keeping the patient on a diet consisting of nothing more than sips of albumin water.

If in a day or two the external wound shows signs of being inflamed, I would at once cut the sutures and drain it. Even if the external wound closes by granulation, the line of union on the mucosa may heal, and the sphincter muscle thus be saved. If the infection breaks through into the bowel, I would at once pass one blade of a pair of scissors, or a bistoury through the opening, divide it with one cut and pack it, when the patient would be no worse off than if an ordinary incision and packing operation along old lines had been done.

[1] Read before the meeting of the American Proctologic Society at Atlantic City, June 8, 1904.

OBSERVATIONS ON THE BLOOD AND CIRCULATION IN UNCINARIASIS.[1]

BY W. G. HARRISON, M.D.,
OF TALLADEGA, ALA.

The admirable work of Dr. C. W. Stiles in establishing the relationship between certain forms of persistent anemia and hookworm has made the latter a subject of increasing interest to the Southern profession. It is here, in the sandy section of our Southern States, that he found this parasite most flourishing and most destructive.

Uncinariasis is rare in clay soils, hence is quite infrequent in the district where I practice, but it has been my fortune to observe some six or seven cases, who are attending the State Schools for Deaf and Blind at Talladega. While fully conscious that we can reach no safe and scientific conclusions from such limited observations, nevertheless I trust this study is of sufficient import to merit your attention.

It might be interesting to review the entire symptomatology and clinical history of the following cases, especially with reference to the peculiar stare, general edema, depraved appetite, etc., but, for the sake of brevity, this report will be limited to observations on the heart, blood and circulation.

Case I.—T. D., white, male, aged sixteen years, Baldwin County, Ala. Point of maximum intensity of apex beat three-quarters inch below and one and a half inch external to nipple lines. Apical thrill, systolic in time. Heart dulness distinct one-half to three-quarters inch to right of right sternal border. Soft blowing systolic aortic murmur, not propagated. Great throbbing of neck vessels. Pulse soft, very compressible rate 122 (standing). Blood pressure 120.

Under use of calomel, santonin and thymol this boy voided over two hundred hookworms, and four months later his examination reveals the following condition:

Point of maximum intensity one-half inch below nipple and in line with it. No apical thrill, no heart dulness to right of sternal border; soft systolic murmur over center of cardiac area, but not propagated. Pulse rate 96 (standing). Blood pressure 145.

Final observation made April, 1904, just eleven months after institution of treatment, reveals the following changes: Point of maximum intensity five-eights inch below and three-quarters inch inside nipple lines. No throbbing of neck vessels, no thrill, no murmur. Pulse 81. Blood pressure 153.

Case II.—White, male, aged ten years, Chambers County, Ala. Point of maximum intensity, one and a half inch below and one inch external to nipple lines. Dulness about one finger's breadth to right of sternal border; no thrill; soft blowing systolic aortic murmur, distinctly propagated to neck vessels. Marked accentuation of pulmonic second sound. Both venous and arterial pulsations in neck. Pulse rate 124. Blood presure 110.

[1] Read before the Medical Association of Alabama, Mobile, Ala., April 18, 1904.

Under treatment similar to Case I, this patient voided 87 worms, and, upon his return to school after the summer vacation (four months later) an examination shows point of maximum intensity three-eighths inch external and one-half inch below nipple lines. Complete disappearance of murmur; no throbbing of neck vessels; no distinct dulness to right of sternal border. Pulse rate 91. Blood pressure 134. No pulmonic accentuation.

Final observation April, 1904, eleven months after treatment: Point of maximum intensity, five-eighths inch below and one-half inch inside nipple line; pulse 79; blood pressure 148. No murmurs and no throbbing.

Case III.—W. J., white, male, aged thirteen years, Henry County, Ala. Point of maximum intensity, 1¼ inch below and 1½ inch external to nipple lines; no dulness to right of sternal border; heaving impulse over entire cardiac area visible several feet distant from patient; systolic thrill over center of heart; accentuated pulmonic second sound is loud and snapping. Rough and harsh aortic murmur, propagated down and to the left; venous and arterial pulsations in the neck; pulse rate 122 (standing); blood pressure 104.

Under hookworm therapy this patient was relieved of more than a thousand worms within three days. When he returned to school, four months later, I then made the following note of his condition: Point of maximum intensity, one-half inch below and three-eighths inch outside nipple lines. Both the thrill and the heaving have disappeared; no cervical pulsations. While the murmur is no longer heard there remains a distinct accentuation of the pulmonic second sound. Pulse rate 85, blood pressure 148. Final observation April, 1904, eleven months after treatment, shows point of maximum intensity three-quarters inch below and three-eighths inch inside nipple lines; all throbbing, murmur and pulsations remain absent. There is now no noticeable accentuation of the pulmonic second sound. Pulse rate 73; blood pressure 156.

I should like to report a few details of other cases, but in these alone was I able to thoroughly study the blood changes, and so other cases must be omitted. I will now give a table showing observations on the blood proper:

	Red Cells.	White Cells	Hemoglobin % (Dare)	Polymorphonuclear acidophiles %	Small Mononuclears %	Large Mononuclears %	Eosinophiles %	Blood Pressure.	Pulse Rate (standing.)
Case I.									
Before treatm't.	1,739,462	5,760	27	59	23	12	5	120	122
4 months after. .	2,643,154	6,835	55	70	20	6	3	145	96
11 months after.	3,469,808	6,462	83	68	18	9	4	153	81
Case II									
Before treatm't.	1,964,750	6,736	29	64	20	8	7	110	124
4 months after. .	2,573,560	6,262	60	65	19	12	4	134	91
11 months after.	4,631,224	7,160	89	66	21	10	3	148	79
Case III.									
Before treatm't.	1,465,790	7,862	21	60	27	9	5	104	127
4 months after. .	2,977,232	6,500	70	62	23	12	3	148	85
11 months after.	4,628,134	6,230	70	71	18	8	3	156	73

The pulse rate was always counted while the patient was standing. In the estimation of hemaglobin the Dare instrument was used. There was slight poikilocytosis in Cases I and II, but none in three. No megaloblasts seen. From a careful study of these cases and a few others observed with reference to these symptoms one seems justified in the following conclusions:

1. Uncinariasis through its extreme anemia exerts a most marked influence on the heart, causing apparent increase in size (most likely dilatation), heaving pulsations, relative insufficiency, thrill and murmurs.

2. While these conditions may be accompanied by an accentuation of the pulmonic second sound, nevertheless they rapidly disappear when the cause of anemia is removed, and by slow degrees the accentuation is likewise obliterated.

3. The murmurs are mostly aortic, soft and blowing, but are both systolic and diastolic, all of which suggests they may be either hemic (due to anemia) or caused by relative insufficiency, result of dilatation.

4. The fact that the area of heart dulness seems to diminish susceptibility after the relief of the anemia, would suggest a marked dilatation, and this seems forcibly strengthened by observations on the blood pressure, which went up from 120 to 153 in the first case; from 110 to 140 in the second and from 104 to 156 in the third.

5. The blood cell changes are not especially significant other than indicating a marked anemia. Many more and oft-repeated observations would be necessary to establish a definite relationship between this anemia and the number of eosinophiles.

6. No megaloblasts found in these cases, as has been the rule in previous work.

7. The rise of blood pressure beginning immediately upon removal of the cause is a safe index to the returning strength of the heart.

8. Even in the most desperate cases we may confidently promise rapid improvement immediately after the removal of the worms.

The medical profession cannot be too grateful for the pioneer work of Dr. Stiles. Heretofore regarded as hopeless and incurable because its etiology was unknown, and its pathology unstudied, uncinariasis, through this investigator's own individual effort, has become one of the most easily recognized and readily curable affections. When we justly laud our own profession, let us not forget to render proper praise to our brother workers in the collateral sciences who, like Dr. Stiles, are blazing new paths for themselves and for us. No achievement in many years is attended with more brilliant results than the recognition and treatment of uncinariasis. Heretofore regarded as malaria, heart disease, or disordered digestion, it is now a distinct medical entity, simple in its diagnosis and still more simple in its relief.

OUR AIMS.[1]

BY S. J. MELTZER, M.D.,
OF NEW YORK.

In discharging the customary obligation of a president to deliver an address at the opening of an annual meeting, I shall follow the frequent custom and confine my remarks to the affairs of the Association.

In electing the present occupant of the presidency you broke away from a proper tradition. The first three presidents were taken from among the founders of the Association. I cannot claim such an honor. I was elected a member, was subsequently put on the Council of the Association in about the same manner as I was honored by the election as president—that is, without having been much consulted about it.

Not knowing very much about the original aims of the Association, nor the particulars of its subsequent history, and there being no published minutes of its proceedings, I have turned to our efficient secretary for some information.

Of the few data now in my possession none is more pleasant and interesting than the fact that neither I nor my predecessors have, or have had, any sad duties to perform. The Association has never yet met with the flag at half mast—for which we are grateful to the fates. But death is not the only decimator of societies. In fact, hardly any society ever dwindles away by the demise of its members. In a thriving society there are always a good many more births than deaths. Whether our Association can be considered as thriving you will know at a glance from the following few figures. According to our secretary, there were at one time supposed to be thirty-nine active members. To-day the Association counts only twenty-nine. That means a loss of 25 per cent. of its membership within the seven years of its existence—and a loss esssentially by resignation.

The Association was organized in 1897 in Philadelphia while the American Medical Association was holding its sessions there. We are again meeting in the shade of this Association, now reorganized and regenerated. Of late years its presidents are no longer merely successful medical politicians, but are leaders in the science and practice of medicine in our country. It was a disappointment to me when I discovered that both present presidents of that leading Association, the retiring president and the president-elect, had been members of our Association and had resigned. What ails our organization? Why do leading clinical men get out of it? There are in the United States many good men who are active workers in the gastro-enterological branch of the practice and science of medicine. Why are they not members of our Association?

Do not accuse me of tactlessness for publicly touching the sore point. In electing me president

[1] President's address, delivered at the opening of the annual meeting of the Gastro-Enterological Association, held in Atlantic City, N. J., June 6, 1904.

of this Association—and I must say without my knowledge and against my wishes—you have given me the privilege, and thus imposed upon me the duty of looking after its welfare, and I can do it only in my own way. I find that the Association is not thriving, is not occupying the proper rank among the high-standing medical fraternities; there must be a cause for it, a pathological focus somewhere. Let me probe for it without regard for the pain which it might give to some of us; it may lead to a radical cure.

What is the aim of our organization? A gastro-enteroligical association might mean a society for the study of the gastro-enteric part of the science and practice of medicine; or it might mean a society of practitioners who make gastro-enteric diseases their specialty. The medical men at large seem to think that our organization is a society of stomach specialists—for stomach specialists; hence their frowning upon its existence. Of the reasons for the disfavor with which such a union is looked upon there are two about which I shall speak. One is that the treatment of the diseases of the gastro-intestinal tract forms an essential part of the activity of the general practitioner, and the separation of this group of diseases into a new specialty is naturally not looked upon by them with favor. The other reason is a more serious one. It must be admitted that there are now in every large city practitioners who pronouncedly make the diseases of the stomach their specialty, and who, by their doubtful activity, throw a discrediting light upon gastro-enterology as a specialty. I am not speaking of the really bad characters. They are too well marked to be confounded with the good and clean men. I am alluding to the men whom we frequently hear speaking in the medical societies, who write numerous articles in the medical journals on some gastro-enterological topic, and who are often credited in the lay press with great discoveries in this specialty. To the undiscerning eye they are the real representatives of gastro-enterology. To the discriminating mind, however, these men and their activity are perfectly transparent. It is nothing but advertising for business sake. They are the men who throw odium upon gastro-enterology as a specialty, and hence the distrust with which the Association of Gastro-Enterology has to grapple.

Are the reasons valid? I shall say no. In the first place our organization is not a society of stomach specialists—for stomach specialists. The Association has in its ranks a goodly number of active members whose practical activity is in the field of general medicine. If the Association had been made up exclusively of stomach specialists, I would not have been its president; I would not have been even a member of it. It is only my very modest scientific activity in our field which brought me into your ranks, and you were liberal enough to honor me with the presidency of the Association, in spite of my published heresies in certain methods of practical therapeutics in diseases of the stomach, for which I still get a gentle rap once in a while from one or the other member of the Association.

No, the aim of our Association is and shall be to bring together all the solid scientific workers in the United States who contribute to the knowledge of the normal and pathological conditions of the gastro-intestinal canal. And there is ample justification for such a union. Many of the most characteristic anatomical, physiological and pathological features of the digestive canal are common to all its parts. But the field is already too large and the problems by far too many to be worked at with profit by a single set of men. One can spend a lifetime in active original work on the motility or the chemistry or the clinical symptomatology of the disorders of only one part of the digestive canal without having accomplished more than one small fraction of his task. At the same time it is indispensable for each student to know and learn the workings of every part of the gut, since they are mostly controlled, at least in a general way, by the same principles. It would be very profitable indeed if all the active students of the workings of the normal and pathological tract: the anatomists, physiologists, pathologists, internists and surgeons would come together, exchange their views and communicate the recent advances made in their respective spheres. The anatomists and physiologists can nowadays learn a good deal from the experience of the intelligent active surgeon. A great deal of benefit can be derived from such a gastro-enterological organization, and there is ample justification for its existence. There can be some discussion as to the advisability of too great a division of labor in the practice of medicine, but there can be no doubt as to the desirability of the division of labor in the study of the science of medicine.

It is our duty, it should be our task, to build up our Association on a high, ideal, scientific basis, and to develop it along the lines we have sketched above. We shall thus dispel all distrust against our organization, and attract to it all the good men who by the nature of their activity belong to us.

Moreover, by so doing we shall also find the means to cope with the evil menacing us by the pernicious activity of the doubtful individuals we have described above. We shall elect to membership only those men whose solid work bears unmistakable witness of their scientific spirit and their scientific worth, and shall exclude such individuals whose prolific writings have the stamp of a pseudo-scientific activity. And, above all, the moral standing of the individual who seeks admission to our ranks should be scrupulously studied. We should shut the door in the face of candidates with any odium upon their activity. Moreover, we should also open the door from the inside for the expulsion of such members whose activity is apt to drag the society down into disrepute, if in spite of all vigilance should such undesirable individuals be found among our ranks. The simple existence of such a paragraph in our

constitution might have a wholesome effect upon the activity of some unprincipled individuals.

For the purpose of attaining the above outlined desirable ends, I recommend in the first place that the president should be empowered to appoint a large committee, say of seven, which shall be entrusted with the proper execution of the following mandates:

A.—To prepare proper amendments to our constitution in which (1) the ideal aims of the Association are set forth in a clear and broad-minded way; (2) the intellectual and moral requirements of candidates are concisely stated; and (3) the provision of methods of punishment should be stated for behavior unbecoming a member of a high-standing medical and scientific society.

B.—To study the good work done on the normal and pathological conditions of the digestive canal, and to persistently urge the men who are doing such work in the United States and Canada to join our Association, provided their moral standing makes them eligible. We should try with perseverance to attract to our ranks good men who are doing creditable work in anatomy, physiology, pathology, internal medicine and surgery of the digestive tract.

I would like also to go on record with another suggestion, which to my mind would tend to solidify and elevate our Association. It is to start an American journal (monthly or quarterly) for Gastro-Enterology, under the careful editorial management of this Association. The original articles should not be too many and only of first order. But the journal should contain a complete classified account of the gastro-enterological literature of this country. Even the sham publications should find a place there, but a fitting one.

However, this suggestion is not offered for its immediate consideration. Elevation, growth and development of our Association should be for the present our first and sole task.

REPORT OF A CASE OF OBSTINATE PHOSPHATIC DIATHESIS CURED BY SYSTEMATIC DILATATIONS OF THE POSTERIOR URETHRA.

BY GEORGE THEODORE MUNDORFF, M.D.,
OF NEW YORK.

In presenting this short communication, the writer proposes to discuss neither the question of the pathology of phosphaturia, save in a brief way, nor the advisability of the use of the urethral dilator as a routine remedy in the treatment of that disease. It is his purpose merely to offer the result of his observations in a case treated by this method, which had resisted all forms of therapy with the exception of the one in question, and to leave the problem of its true therapeutic value a matter for independent judgment and further experimentation.

It is but fair to state that the case about to be reported was not one of true phosphaturia,—an actual increase in the elimination of phosphoric acid,—but a form of so-called phosphaturia with alkaline urine and the consequent precipitation of the phosphates, which is so often met with in neurasthenics with gastric disturbances. In many respects it did resemble the class of cases to which Tessier has applied the term "phosphatic diabetes" in which phosphaturia and polyuria are combined with loss of flesh and strength. There was great general debility and indigestion, associated with an impaired tone of the nervous system, aching pains in the back and limbs, and on two occasions while under treatment, the patient presented a crop of boils on his neck and arms. The patient, too, excreted an excessive amount of urine, the daily average amounting to a little over ninety ounces. Occasionally, the phosphatic precipitate would represent one-eighth to one-sixth of the entire bulk. The history of the case is as follows:

Case.—Mr. J. W., age thirty-eight years, married, engaged in a large mercantile business, consulted the writer during the fall of 1902. Family and personal history negative, save that the patient admitted having had a gonorrhea some six or seven years ago. This was treated in the usual way by means of internal and local medication, and was cured in about four months. About five years ago, he became allied with a very large mercantile house, and soon assumed a considerable share of its financial responsibilities. In a short time, he began to complain of great nervousness, confusion of mind, irritability and depression of spirits. At this time he noticed that he was passing a large quantity of urine. This did not give him much concern, since he referred to it as a symptom of nervousness. He became alarmed, however, when he observed later that the urine was of a milky color. This peculiarity prompted him to consult his physician. The urine was examined, and was pronounced as containing phosphates. The patient was given mineral acids, and was advised to eat sparingly of meat. Sexual intercourse, too, was in great part interdicted.

No improvement followed this plan of treatment. He was now given benzoic acid in fairly large doses, and advised to take a sea voyage. He remained away from business nearly two months, and, notwithstanding his observing every feature as to proper diet, exercise and medication, continued to grow worse. The glycero-phosphates were now administered, and while the appetite was somewhat encouraged, the condition of the urine remained unchanged. At times, the patient suffered from insomnia, and he was compelled to resort to some of the bromides to obtain relief. His duties at the office were now very much curtailed, and his business hours considerably lessened. He made it a practice, too, to leave the city for a few days every two or three weeks.

Everything was now done that tended to increase the general vigor. Systematic exercise in the open air, and sea-bathing were recommended, and appeared to produce a happy re-

sult. The patient gained in weight, the appetite was increased, and there was a decided change in the general condition. The urine, though, was still loaded with phosphates. Small phosphatic calculi about the size of a small pea were occasionally voided with the urine. The patient was now informed to resume his former work, and was given some bitter tonic. He presented himself at regular intervals for over two years, during which time the daily amount of urine steadily increased; the phosphatic sediment, too, became greater. The general condition was good. It was about this time that the patient came under the observation of the writer.

Status.—Heart and lungs normal; liver not enlarged. No urethral discharge. Prostate slightly enlarged and moderately sensitive. Urine, turbid; upon standing for a few minutes, a heavy white sediment quickly forms. The urine is alkaline in reaction; the specific gravity is 1028; no albumin; no sugar. A small portion of the sediment was examined under the microscope, and found to be composed mainly of the ammoniomagnesian or triple phosphates. There were no pus cells. To determine roughly the proportion of the earthy phosphates, a few drops of ammonia were added to a test-tubeful of the urine. A white precipitate about 5½ c. high was produced, which was not dissolved by heat. In an ordinary-sized test-tube a deposit one centimeter high represents a normal amount. While a sediment of the earthy phosphates does not necessarily indicate that there is an abnormal amount in the urine, it does, however, show the alkaline state of the urine and the possible outcome of such a condition, and it also points out the possible danger of phosphatic calculi formation.

After having filtered out the precipitated earthy phosphates, a small quantity of a saturated solution of magnesium sulphate was added to the same urine in order to estimate roughly the amount of the alkaline phosphates—sodium and potassium phosphates. A milky turbidity of the fluid followed, which may or may not have indicated an excess of the alkaline phosphates. Unfortunately, at no time while the patient was under professional care, was any attempt made to ascertain the quantity of phosphoric acid in the urine. Normally, the average quantity passed by an adult in twenty-four hours is, according to Vogel, about 50 to 53 grains. Whether there was an excess in this case is not known.

Examination for stricture of the urethra proved negative.

Therapy.—The patient was given dilute phosphoric acid, ten to fifteen drops in water shortly after meals. The bladder was irrigated with a mild solution of boric acid two or three times a week. In the way of hygiene everything was suggested that tended to improve the general vigor. Animal food was to be taken with each meal. This was about the general outline of the treatment for nearly five months. Internal medication consisted in the administration of the different mineral acids, benzoic acid, cod-liver oil emulsified with hypophosphites and containing iron, ammonium benzoate and salol. Each in turn was given a fair trial, and each proved ineffectual. The patient gradually grew worse. On two occasions, crops of boils appeared and required lancing. Sugar was never found in the urine. Cystoscopy was performed on several occasions, and revealed a thickened trabeculated condition of the bladder wall. No stones were found. The prostate appeared to be enlarged.

Subsequent Treatment.—Having observed a few instances of "phosphaturia" in cases of retention of urine due to temporary or permanent paralysis of the bladder, as in hemiplegia and paraplegia as well as in cases of prostatic hypertrophy, and recalling the effects of the same treatment in another similar case, the writer was prompted to give posterior dilatations of the urethra and with it dilatations of the internal sphincter a trial in the case under discussion. Kollmann's posterior dilator was used for the purpose. Dilatations were made once every week, and irrigations of the bladder with a mild boric acid or silver nitrate solutions were made a few days after each dilatation. It was remarkable to observe the decided change for the better that occurred after a few treatments by this method. The patient's spirits became brighter, and the turbidity of the urine gradually disappeared. In eight weeks, the urine was absolutely clear. Dilatations were continued for another four weeks, at the end of which time the patient was discharged cured. Since then the writer has seen him at regular intervals, and at no time has there been a return of the old complaint.

About six years ago the author had a similar case under his care. In this instance, there was a stricture of the urethra. Its caliber permitted the introduction of an 18 F. sound. After some preparatory dilatation, it was possible to introduce the regular Kollman dilator. This form of treatment produced in a most striking manner a decided amelioration of the phosphatic condition. Encouraged by this result, the writer began systematic dilatation of the posterior urethra. While an improvement followed, it was not permanent, and the patient finally discontinued his calls at the office.

Without in the least indulging in the luxury of conjecture, the writer desires to express his view as to the *modus operandi* of posterior urethral dilatation in affecting the decided relief in the case here reported. It is well known that a hyperemic or chronically inflamed condition of the prostatic urethra often produces marked neurasthenic symptoms. The nerve supply of this region is exceedingly rich. The bladder, seminal vesicles and the prostate receive filaments from the vesical plexus, which, in turn, is made up of numerous branches from the hypogastric branch of the sympathetic, together with branches from

the sacral ganglia and from the pudendal plexus of the sacral nerves. Any irritation of this locality is sufficient to excite functional disturbances of distant organs. The general symptoms are those of neurasthenia. Is it not possible that the phosphatic condition of the urine is due to some reflex secretive anomaly of the kidney?

Accepting these premises, it is fair to conclude that our patient was suffering from some inflammatory condition of the posterior urethra. The patient had had a gonorrhea, and, as has been already mentioned, there was some enlargement of the prostate gland. Local treatment of the prostatic urethra by means of direct applications of strong solutions of nitrate of silver and the passage of sounds are effective means of relieving congestion, and thus restoring the muscular tone of the adjacent organs. In our case, the posterior dilator, as devised by Arthur Kollman, of Leipzig, was employed, an instrument far superior to the ordinary sound.

304 Second Avenue.

MEDICAL PROGRESS.

PHYSIOLOGY.

The Effect of Alcohol upon the Excretion of Uric Acid.—A consideration of the results of his experiments leads S. P. Beebe (*Am. Jour. Physiol.*, September 1, 1904, to conclude that it is hardly possible to doubt that alcohol, even in what is considered by the most conservative as a moderate amount, causes an increase in the excretion of uric acid. This effect is seen almost immediately after taking the alcohol. That the above is due to toxic effect in the liver, thereby interfering with the oxidation of the uric acid derived from the precursors in the food, is indicated by the following points: Alcohol taken without food causes no increase; if the food contains less purin there is a smaller increase in excretion; the maximum increase takes place at the same time after a meal as when purin food but no alcohol is taken; the purin bases are effected to the same degree as the uric acid; alcohol is rapidly absorbed and passes at once to the liver, the organ which has most to do with the metabolism of proteid cleavage products. There is no evidence that the alcohol has merely hastened the excretion of urates normally present in the blood; the increased excretion means that a larger quantity has been in circulation, which might be harmful in pathological conditions. The author believes that if the origin of the increased quantity of uric acid be attributed to the impaired oxidative powers of the liver, the results of these experiments will have greater significance than if attributed to uric acid alone. For the impaired function would affect other processes, which are normally accomplished by that organ, and the possibilities for the entrance into the general circulation of toxic substances, of intestinal putrefaction, for instance, would be increased. The liver performs a large number of oxidations and syntheses designed to keep toxic substances from reaching the body tissues, and if alcohol, in the moderate quantity which caused the increase in the uric acid excretion, impairs its power in this respect, the prevalent ideas regarding the harmlessness of moderate drinking need revision. Alcohol is a food in the sense that when used in small quantities the energy from its oxidation may be used for some of the body needs, but since, at the same time, it interferes with the normal activities of a most important organ, its food-value may be counterbalanced by its toxic effect. Salt water may be used in a steam-boiler, and the steam from its evaporation may transmit the energy of the fuel to the revolving wheels, but its corrosive action on the steel forbids its use, like alcohol, except in emergencies.

Contributions to the Knowledge of Ferments.—The decomposition of peroxide of hydrogen on contact with platinum has been called a catalytic effect; and it has been supposed that the catalytic agent acts by virtue of its attraction for one of the atoms in the unstable molecule. Of no uncertain importance from the standpoint of the physiological significance of ferments are the researches of L. Liebermann upon the nature of catalysis by means of colloidal platinum (*Pflüger's Archiv.*, August 15, 1904). The author finds that solutions of colloidal platinum contain active oxygen. The latter may be partly renewed or rendered inactive by means of heating or by means of gases, such as hydrogen and nitrogen. Hydrogen powerfully damages and causes a peculiar change in the colloidal solutions of platinum, as evidenced by the changed color of the latter. If kept in contact with air or oxygen, solutions of colloidal platinum resist the action of heat a longer time than if in contact with such indifferent gases as hydrogen and nitrogen. From this fact the conclusion is drawn that in the catalysis of H_2O_2, oxygen plays an important rôle; the colloidal solutions of platinum possess the capacity of activating molecular oxygen. It would seem as if loose compounds of platinum and oxygen are formed. Up to a certain limit the catalytic action of colloidal platinum upon H_2O_2 is increased if a stream of hydrogen is caused to flow through it. The faster the stream the stronger will the catalysis afterward be. A quantity of hydrogen too great has exactly the opposite effect. The introduction of nitrogen likewise increases the catalytic effect. This increase is attributed to the mechanical agitation produced by the streaming gas, which, by breaking up larger measures of the platinum, renders this capable of uniting with a large amount of oxygen. Ozonized air markedly impairs the activity of colloidal platinum. The animal tissues, such as cartilage, brain-substance, vitreous humour and the crystalline lens and fatty tissue, contain substances, obtained in watery extracts of the tissues, which bring about the catalysis of H_2O_2. These extracts, like those obtained from malt, which also contain similar catalytic agents, contain very little active oxygen. But the former, unlike the latter, do not give the guaiac reaction, which shows that the catalysis of H_2O_2 and the guaiac reaction are due to distinct ferments. The guaiac reaction is as follows: If an alcoholic solution of guaiac resin is mixed with watery solutions of various animal and vegetable substances, or with certain inorganic substances (ferric chloride, etc.), there results a blue coloration. Since it has been shown that this reaction occurs in the presence of oxidizing substances, it follows that in the case of the plant and animal tissues that give the reaction, oxygen must be present. The mechanism of the guaiac reaction seems to consist in a union of guaiac with molecular oxygen and the release of active or atomic oxygen in the presence of an oxidizable surface. This capacity, possessed not only by guaiac resin, but also by many other substances, is probably bound up with the large extent of surface represented in the very fine particles present in solution, the surface attraction of which is capable of tearing asunder the constituents of the inactive oxygen molecule. The active oxygen atom thus liberated is, however, still bound up to such an extent that it can-

not be driven out by gases that are inactive with respect to guaiac tincture. In order to bring about the rapid oxidation of guaiaconic acid, a catalytic agent or ferment is necessary. This catalyser operates by uniting, if only for a moment, with active oxygen, and transferring it from one group of guaiac to another, guaiaconic acid, to whose oxidation the blue coloration is attributed. The guaiac reaction thus throws light upon the mechanism of enzyme action. But it is interesting from another point of view. It helps to explain certain phenomena conected with the destruction of certain foreign and toxic bodies in the organism. Certain pathogenic bacteria can be rendered innocuous by the protective bodies normally present in the organism, only by uniting with these bodies. Buchner calls these protective bodies alexins, and Ehrlich complements. These substances act so slowly that they cannot fortify the organism against an intoxication. On this account another body is necessary, the immune body (amboceptor, matière sensibilisatrice), which will unfold the activity of the alexin or alexins. Only by means of these immune bodies are the protective substances in a condition to neutralize the toxins before they can bring about a general poisoning of the system. The analogy to the phenomena of the guaiac reaction is as follows: The pathogenic agent corresponds to the guaiac, the alexin to the active oxygen, and the immune body to the enzyme. The immune body is nothing more than a catalyser. The specificity of the actions of the immune bodies might depend upon the fact that the foreign agents (bacteria or otherwise) prepare, from some part of the organism or from themselves, an immune body (catalyser) which will hasten the reaction between the protective body and its own toxin. In this respect there is no analogy to the guaiac reaction.

The Combined Action of Proteolytic Enzymes.—A series of experiments were conducted by P. A. Levene and L. B. Stookey (*Am. Jour. Physiol.*, September 1, 1904), with the view of determining the combined action of various proteolytic enzymes. The observations were made on the combined action of spleen and pancreas, and of spleen and liver. The action either of the minced glands or of extracts of the same was studied. It was found that when spleen and pancreas were allowed to act simultaneously on a foreign proteid, —egg albumin or casein,—the quantity of products of digestion resulting from their action was greater than the total sum of products obtained by the digestion of equal quantities of spleen and pancreas acting separately. It was thus not a summation of the action of two enzymes, but an increase in the digesting energy of one or both. From the results of some of the experiments the increased action might be attributed to the pancreas. Thus when three parts of pancreas and one part of spleen were allowed to act on a foreign proteid, the quantity of digestion products was greater than in the experiments where pancreas and spleen were taken in equal proportions or in proportion of one part pancreas to three of spleen. In another experiment, fresh pancreas was allowed to stand under antiseptic precautions for about forty-eight hours at room-temperature. At the end of that time, all the zymogen of the gland presumably is transformed into enzyme. Fresh spleen was added, and their combined action in foreign proteid was not noticeably greater than an equal portion of pancreas similarly treated and an equal quantity of spleen acting separately. These experiments, the authors believe, seem to corroborate the views of Schiff, Herzen, and Mendel and Rettiger, namely, that the spleen facilitates the transformation of the pancreatic zymogen into the active enzyme.

MEDICINE.

Agglutination With Icterus.—Many observations have been made, and much has been written upon positive typhoid agglutination where typhoid could be positively excluded, but where a more or less intense jaundice was present. Many explanations have been given, and it is therefore gratifying that H. Lüdke (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 1 and 2), has tested a large number of cases, to determine the cause of the clumping. In seven out of nine cases of catarrhal jaundice a distinct agglutination in a dilution of one to forty was obtained, but most cases of carcinoma congestion, cirrhosis, abscess, fatty degeneration and amyloidosis of the liver were negative, even though the jaundice at times was most intense. All in all, 36 liver cases were examined; of these 32 were icteric, but only 19 showed clumping in a dilution of 1:20 and 11 in a dilution of 1:50 or over. Seven cases of icterus neonatorum gave negative results, but in a number of other diseases (nephritis, diabetes), a very feeble agglutination could be obtained. All positive icteric cases were also tested with bacteria allied to the typhoid bacillus, with the result that the *Bacillus coli*, paratyphoid and vulgare were also aggutinated, but less strongly, except in Weil's disease, which seems to stand in special etiological relation to the *Proteus*.

Bile and its constitutents or the serum of animals treated therewith, had no particular influence; where some agglutination was present, it could be proved that this was a property inherent to the normal serum of that particular animal. Artificial jaundice induced by toluylendiamin, inhalations of arseniuretted hydrogen or injections of ether had very little influence upon the serum in its behavior toward typhoid bacilli. Agglutination may thus occur under three conditions: (1) In typhoid, where it is invariably most rapid and pronounced. (2) In infections with an allied germ, especially in catarrhal jaundice, cholelithiasis and Weil's disease (group-agglutination). (3) Owing to a disturbed composition of the blood. The Widal reaction can thus be no longer looked upon as a specific reaction, though it will still continue to be valuable for the diagnosis of typhoid fever.

Symptomatology of Arteriosclerosis.—Based upon the careful analysis of 54 cases of arteriosclerosis of the arota, not complicated by aortic stenosis, aneurism, coronary sclerosis or nephritis, A. Bittdorf (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 1 and 2), gives the following account of the symptoms: Frequently the face is remarkably pale, often of ashen hue, though sometimes the patients appear decidedly plethoric. There is often a tendency toward obesity and the pupils may differ in size, though their reflexes are normal and no pathological lesions were found in the retina. Abnormal pulsations in the subclavian and corotid vessels are generally very evident, but do not differ from those of chlorosis or aortic valve disease. Phlebectasiæ upon the anterior chest wall may be uni- or bilaterial or may appear only with forced respiration; occasionally they are accompanied by a moderate edema over the upper part of the sternum, such as is sometimes described with aneurism. Respiratory symptoms are signs of pulmonary emphysema, tendency toward catarrh, diffuse dilatation of the bronchi with hemoptyses and an increased susceptibility toward tuberculosis. Cardiac hypertrophy is a very common sign; the first aortic sound is distinct and clear, the second accen-

tuated and often there is slight but distinct dulness over the manubrium sterni corresponding to the second rib on the right side. Rarely systolic pulsation is seen in the second right interspace. The peripheral vessels show slight or moderate arteriosclerosis, and it is not uncommon to find slight differences in the pulse of both sides. Pulsus celer is common, pulsus tardus and paradoxus, rare. The blood-pressure is generally above normal. A valuable aid in diagnosis is the examination with the Roentgen ray, since the dilatation of the aorta resulting from loss of elasticity, will give rise to a very distinct shadow. Less common signs are retinal hemorrhages, embolism of the retinal vessels, glaucoma, dyspeptic disturbances. The patients generally complain of palpitation of the heart and cardiac oppression after exertion, dyspnea, attacks of vertigo, owing to deficient blood-supply of the brain, tinnitus aurium, feeling of weakness in the arms and sometimes tenderness on percussing the upper sternum.

Fatal Case of Boric Acid Poisoning.—The popular fallacy that boric acid is innocuous to the system is contradicted by the report of a case by C. I. Best (*Jour. Am. Med. Ass'n*, September 17, 1904), which constitutes the fifth thus far announced in the literature. The patient presented a suppurative inguinal adenitis, otitis media and mastoiditis. The inguinal glands were excised and the cavity packed with about six ounces of boric acid powder. Soon after the operation the man developed the typical signs of boric acid poisoning,—profuse vomiting, a papular rash over the face, neck and chest, and a weak irregular pulse. The onset was rapid and the fatal issue came on within four days. There was also delirium and slight rise of temperature. Post-mortem examination showed congestion of the liver, spleen and gastro-intestinal tract, and a cloudy swelling and granular degeneration of the liver and kidney cells. There were also supericardial hemorrhages, together with discoloration and maceration of the tissues about the cavity in which the boric acid was placed. These findings limit the cause of death to one of two things: A toxemia, resulting from the abscess in the groin, or from the medicinal agent employed, as other recognizable causes were not present. Its resemblance to other cases previously reported, together with the demonstrated overuse of the drug, was sufficient for the diagnosis. The clinical features and the lack of success in cultivating pathogenic bacteria from the blood eliminate septicemia, which is the condition most likely to be simulated in such a case.

Multiple Myelomata.—A very remarkable case of multiple myelomata of the bones, has been observed by A. Scheere and L. Herxheimer, (*Zeitschr. f. klin. Med.*, Vol. 54. Nos. 1 and 2). The patient had been suffering for a long time from vague pains in different parts of the body and had been treated for rheumatism by all who had seen him, until with a slight twisting motion of the body, a fracture of the neck of the femur occurred. Even now there was some hesitancy as to the diagnosis since at no time were Bence-Jones bodies found in the urine.

The Roentgen rays, however, gave a clear picture of the condition of the femur and of other bones, and left no doubt that a serious bone-trouble was present. Other symptoms were an irregular remittent fever and a consecutive anemia. The number of leucocytes present was always normal. At autopsy it was found that the neoplasms had affected a large part of the entire skeleton without causing metastases elsewhere.

PATHOLOGY AND BACTERIOLOGY.

Bence-Jones Albumin.—In a case of multiple myelomata examined by L. Lindemann (*Deutsch. Arch. f. klin. Med.*, Vol. 8, Nos. 1 and 2), the urine presented the following reactions: When warmed up to 60° to 65° C., a tenacious precipitate appeared, which partially dissolved on boiling, and reappeared on cooling. Nitric and muriatic acids give rise to a precipitate in the cold, which also dissolved on boiling. The same was true of tannin and acetic acid and of picric acid. Millon's, Adamkiewicz's and Moluch's reaction were positive. The amount of proteid excreted was on the average 2 pro mille. Careful chemical examination showed that the body is more closely allied to albumins than to albumoses, and that it corresponds closely in chemical composition to the proteid excreted in other cases of myeloma previously published.

Changes of the Pancreas in Arteriosclerosis.—Arteriosclerotic changes in the pancreas, in the form of thickening of the intima, more rarely the media of the vessels and thrombosis, are almost invariably found in diabetes, according to G. Hoppe-Seyler (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 1 and 2). In patients not suffering from glycosuria, arteriosclerosis may also occur, but here the islands of Langerhans are spared, while in diabetes they may be entirely sclerotic or filled with hyaline masses. There seems to be a direct proportion between the severity of the diabetes and the extent of lesion here. Pancreatic changes secondary to cirrhosis of the liver consist chiefly of a perilobular or periacinous connective tissue proliferation which does not involve the islands. In syphilis, the vessels are generally much altered, and the connective tissue strands are thick and penetrate into the interior of the lobules. The condition of the islands will depend upon the presence or absence of sugar in the urine. Other forms of cirrhosis of the pancreas are granular atrophy, analogous to granular atrophy of the kidney and interstitial pancreatitis, starting from the pancreatic ducts. No matter what the type of lesion, the close relation between the condition of the islands and glycosuria, is always evident. Anatomically these resemble closely the glomeruli of the kidneys. Diabetes must thus be regarded as a special manifestation of arteriosclerosis. Other manifestations of arteriosclerosis need not be present, though frequently enough thickened radial arteries, hypertrophy of the left ventricle and albumin in the urine, may be found. If intercurrent disease or arteriosclerosis of some other organ does not kill, the patient will eventually die in coma, since the condition is progressive. Early stages are generally overlooked, since other signs of arteriosclerosis predominate at first. It is odd that even with advanced pancreatic diabetes, symptoms of deficient pancreatic digestion, such as fatty stools or an abundance of muscle fibers in the feces, are usually absent. Alimentary glycosuria can be induced more readily in persons whose vessels are normal, especially if alcoholism is present. The author believes that the test for alimentary glycosuria should be made in all cases of arteriosclerosis, since in its early stages it may be possible to check the process.

Ossification of Lymph-Nodes.—O. Lubarsch (*Virchow's Archiv*, Vol. 177, No. 3), has examined a large number of lymph-nodes at autopsies and has been surprised to find ossification of frequent occurrence, especially when the glands were formerly the seat of a tuberculosis. He believes that the bone results from

metaplasia of the connective tissue capsule which surrounds the cheesy focus and that the deposit of lime salts in the necrotic tissue forms the starting point. Cartilage and bone are also frequently found in the tonsils, in part due to fetal inclusions of cartilage, in part as a result of the presence of inflamed connective tissue. A. Rückert (*Virchow's Archiv*, Vol. 177, No. 3), believes, however, that bony tissue within the tonsils is derived solely from rudiments of the second pharyngeal cartilege, and that metaplasia of connective tissue does not play a prominent part.

Pathology of Myxedema.—A case of myxedema studied by A. I. Abrikossoff (*Virchow's Archiv*, Vol. 177, No. 3), presented the following interesting lessons at autopsy: The thyroid was completely replaced by fatty and connective tissue, developed undoubtedly after birth, since contours, size and position of the gland were normal, and an acinous distribution was still evident. The hypophysis showed considerable hypertrophy of its anterior portion, the chromophile cell particularly manifesting an increase in size and number, with considerable colloid degeneration. These changes were probably compensatory, since the nuclei were well-preserved and the vessels were everywhere filled with blood.

Chemistry of Tuberculous Tissue.—A large amount of tissue, which had undergone complete cheesy degeneration, was subjected by E. Schmoll (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 1 and 2), to chemical analysis. He concludes that the chief percentage consists of coagulated albumin, whose proteid nature is undoubted since pepsin and hydrochloric acid will convert it into albumose and peptone, and since hydrolytic decomposition will give rise to the typical principles of proteid disintegration. The elementary analysis also resembles that of albumin. The ordinary solvents of proteids do not dissolve it. Nuclear elements could not be detected since these are probably dissolved out as the cytoplasm coagulates.

The Pathology of the Cells of the Sensory Ganglia.—In order to clear up many of the conflicting points concerning the changes that occur in the sensory ganglia cells following section or injury of their peripheral axons, a series of experiments were conducted by E. Lugaro. (*Arch. Ital. de Biol.*, May 31, 1904). The classical type of these changes, as originally described by Nissl, consists of a breaking up of the chromatic substance into distinct masses, beginning at the center of the cell and proceeding toward the periphery, frequently not affecting the marginal portion of the cell, and also accompanied by a displacement of the nucleus toward the periphery with an occasional irregularity of the nucleus. The various types of cells in the sensory ganglia may be considered specifically distinct, both anatomically and physiologically. Following section of the peripheral nerves, these different kinds of cells show a reaction different in type, intensity and promptness. Cells of the same type in different animals react differently. The smaller cells are the first to react and the first to undergo repair. In the plexiform ganglion of the vagus the reaction is more plexiform than in the spinal ganglia. Even though the nerve is put into such a condition that it cannot reestablish its primitive connections with the periphery, reparative processes nevertheless take place always in the sensory ganglia, but not in all the cells. Some of the cells may degenerate. The proportion of the latter varies in the different animals and in the different ganglia, being greatest in the plexiform ganglion of the vagus. The destructive processes that affect the peripheral fibers do not cause any reactive phenomena in the cells that surround the capsules of the nerve-cells; the proliferation of the former and their ability to devour the nerve-cells are really determined by stimuli other than those associated with the reactive phenomena in the nerve-cells. If the lesion of the nerve prevents any re-establishment of its peripheral connections, the corresponding cells, although undergoing repair, present a marked progressive atrophy. In the reaction of the cell to an injury of its neuraxon, the nucleolus becomes hypertrophic. This change, probably an index of the increased trophic activity of the cell, continues during the stage of repair and consecutive atrophy. The cellular modifications caused by section of the nerves represent a rejuvenescence of the cell—an exceptional awakening of the trophic power of the cell during the regeneration of the nerve fiber. These morphological modifications are analogous to those that occur in the embryonic development of the cell, as well as those that are found in the lower orders of animal life.

Cytodiagnosis in Nervous Disease.—Wherever cerebrospinal fluid is to be examined for cellular elements, it should be centrifuged for at least fifteen to thirty minutes. After the supernatant fluid has been poured off, the sediment is taken up by means of a pipette, but sometimes, where no sediment is visible, it is better to pour the entire residue on a glass slide. The simplest and best stain to use is methylene blue. Three to five lymphocytes in one field of the microscope with a magnifying power of 400 to 500 may be regarded as normal, while in pathological conditions four to five to many dozens may be counted. O. Niedner and G. L. Mamlock (*Zeitsch. f. klin. Med.*, Vol. 54, Nos. 1 and 2), have examined the sediment in a number of nervous diseases and report as follows: In nine cases of tabes, hyperlymphocytosis was found five times; in one the lymphocytes were increased only when a gastric crisis came on. Lymphocytosis was also present in four out of six cases of hemiplegia and each one of these four gave a distinct history of syphilis. In a number of other severe, cerebral conditions, the cells in the spinal fluid were not increased. A microscopical examination of the sediment is thus of the greatest value in the diagnosis of syphilitic or metasyphilitic affections of the central nervous system.

THERAPEUTICS.

Urotropin and Helmitol.—The properties of urotropin, as uric acid solvent and urinary antiseptic, are almost solely due to small amounts of formalin, which are split off both in acid and alkaline solution. It is, therefore, invaluable in acute and chronic cystitis, pyelonephritis, pyelitis and posterior urethritis, in typhoid infection of the bladder, to prevent nephritis in scarlet fever, after the use of instruments and in phosphaturia. The urine of patients who have taken urotropin will become ammoniacal less readily if kept than normal urine. A comparatively new compound is the methylene-citric acid salt, known as helmitol. It is said to be superior, since decomposition occurs less readily and the acid radical itself is a derivative of formalin. According to A. Nicolaier (*Deutsch. Arch. f. klin. Med.*, Vol. 81, Nos. 1 and 2) helmitol does not, however, possess any therapeutic advantages, for cases that do not yield to urotropin are not much benefited by this derivative. It is more expensive, since larger doses are required,

and the acid radical occasionally manifests toxic properties such as gastro-intestinal disturbance and eczema. The bromine water and Joressen tests for formalin in the urine are equally marked after corresponding doses of the two drugs, and the urine after the use of helmitol does not inhibit the development of bacteria any longer than with urotropin. Since helmitol is twice as expensive as urotropin, the latter should be given in all cases.

Nasal Hydrotherapy.—Nasal hydrotherapy has for its object a modification of the condition of the mucous membrane by more or less prolonged contact with medicated fluid or by the action of the temperature of a fluid; the removal of the more or less viscous secretions in the rhinopharynx; the obtaining of a violent propulsive action to drive out a foreign body or a pathological product formed in situ. With these objects in view, A. Courtade (*Arch. Inter. de Lary. d'Otol. et de Rhin.*, July-August 1904), defines the terms balneation, irrigation and douche as follows: Balneation is filling the rhinopharynx with mineral, medicated, or waters with a modified temperature without a continuous current. Irrigation is represented by running liquid with feeble pressure, allowing no stagnation of the liquid, as in balneation. Douche signifies an elevated pressure made use of to expel foreign bodies, or pathological products. The irrigation is the ordinary form, the douche being rarely used. In acute coryza, if taken within twenty-four to forty-eight hours of the onset, a half liter irrigation of saline or borated water used morning and evening at a temperature of 48° to 50° C., is often able to stop the coryza in two days; if delayed longer, a cure is not to be expected, although the cause of the disease will be lessened in severity. In the period of decline, when the secretion is mucopurulent and thick, a morning irrigation with saline or alkaline water, an evening irrigation of borated water at the temperature indicated, renders a great service in cleaning out the mucopus adhering to the walls of the pharynx, and constitutes the best prophylactic treatment against otitis media resulting from acute rhinitis, and also prevents extension of the process to the pharynx and bronchi. In coryza good results are reported from the irrigation with milk morning and evening. One case is reported where 25 liters were employed instead of milk, which was used as early as 1864 by Thudicum, a solution of boric acid, chloride of zinc and bicarbonate of soda aa 0.40 centigram, dissolved in a half glass of tepid water, may be used as a nasal bath. Ozena is undoubtedly best treated by the nasal irrigation. The benefit seems to be derived from the quantity rather than the kind of liquid employed. To give one of these large irrigations of 25 liters, two liters of the fluid are sufficient, the reservoir being filled and refilled with the medication already used. An excellent plan is to allow the fluid to run slowly at first to soften the crusts, followed by a more forceful stream to remove them.

The Treatment of Dysentery.—The results of eight years' experience in the treatment of dysentery as practised by the author in the Far East are embodied by J. S. Kolbassenko, in No. 21, *Prak. Vrach.*, 1904. In the way of prophylaxis he considers as the most important the following: (1) avoid overexertion; (2) supply the most nutritious food available, and (3) the best drinkable water. In cases of slight or moderate severity the diet should be fluid and bland; apply a warm abdominal bandage made preferably with alcohol of 70° to 80°. If possible give the following emulsion:

℞ Emuls. ol. ricini 180.0
Tinct. iodi ..... gtt. xx.
Ol. menthæ
Ol. cinnamomi aa..... gtt. vi.
Chlorof ..... gtt. xv.
Syr. emulsivi..... 20.0
M. D. S. A tablespoonful every hour.

Instead of this, one or two tablespoonfuls of castor oil may be administered, with 8 to 10 drops of the iodine tincture or with iodine starch. This is best prepared from potato starch, and presents an almost tasteless and odorless powder of a dark violet or almost black color that is palatable enough even for children. The author relies greatly upon this preparation in the subsequent treatment of the disease, for administered together with the castor oil the iodated starch is evidently not decomposed in the stomach and reaches the smaller and possibly also the large intestines unchanged. It is here that decomposition begins, the liberated iodine acting principally as an astringent and rendering harmless the specific as well as the other toxins that are at the bottom of the trouble. This iodated starch, by the way, is an excellent remedy also in ordinary diarrhea, in infantile diarrhea, as well as in typhoid fever. The preparation should also be introduced into the rectum either in the form of small warm starch injections, or with the addition to them of 20 to 30 drops of tincture of iodine, once or twice a day, to be retained for ten to twelve minutes, or more if possible. After the acuteness of the attack has subsided somewhat, but the ulcerations in the intestines have not disappeared (as evidenced by tenesmus, etc.) the author obtained splendid results from the administration of a following suppository: ℞ Ichthyol—gttas ii—viii (in accordance with the sensitiveness of the intestine to this drug); xeroform, gr. v—viii; antipyrine, gr. vi—viii; bismuth subnitr., gr. xv.—xx.; lanoline and cacao butter each q. s. ut ft. supposit. D. t. No. 10 S. One or two daily. In case of great intestinal irritability it is advisable to add from gr. 1-3 to gr. ½ of the extract of opium or belladonna. As to the action of the drugs the author considers ichthyol as an astringent and disinfectant, xeroform as exciting a favorable effect on the ulcerated surfaces, antipyrine as a powerful astringent and analgesic, and the bismuth reinforcing the action of the xeroform; the suppository has also been found of undoubted benefit in hæmorrhoids. He also obtained good results from warm or even hot injections of water and 20 to 30 drops of creolin, which is too irritating at times, and cannot be retained by the bowels; and it becomes necessary to diminish the dose to a few drops per injection.

Syphilis in the Higher Apes.—A report was published several months ago containing an account of the successful inoculation of a chimpanzee with syphilitic virus from human sources. D. Lasar (*Berl. klin. Woch.*, July 25, 1904), now states that he also succeeded in inoculating a second chimpanzee with virus obtained from the first. The resulting eruption was in the form a generalized papular syphilide and is well shown in a number of photographs which accompany the article. The animal died shortly after with acute miliary tuberculosis and the diagnosis could be verified by microscopical examination of the papules. Lassar claims that this observation demonstrates conclusively that infection of the higher apes with syphilis is possible, and that this animal may serve as a test object, as it were, for the virus and perhaps permit of the production of a specific serum.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, OCTOBER 1, 1904.

THE PROPHYLAXIS OF MALARIA.

The subject of malarial infection is one of no little moment to the physicians of the United States. According to the best information obtainable, the last Census Reports, that in the year 1900 14,874 deaths occurred from this disease with a general incidence of 14.9 deaths in every thousand.

While the incidence of deaths per thousand in 1900 is as 14.9 to 22.1 for the decennial revision of 1890, 14,874 deaths in one year from a preventable disease is a severe indictment of the community, from which the physicians cannot hope to escape entirely.

It is known that for the census year 1900 the death rate from malarial fever was nearly ten times as high among the colored as it was among the whites; and that the highest death rates were in the Southern States, while in the States of Maine and Vermont there were no deaths from malaria in 1890. In all those States, called "Registration States" by the director of the census, because of the completeness of the reports kept by their respective health boards, the death-rate from malarial fever decreased very markedly. But in the non-registration States, particularly the South, the mortality remained higher than it should.

In view of the recent epidemiological work of the various European commissions, the experiences detailed in the recent discussion on the prophylaxis of malaria, held at the last meeting of the British Medical Association, should not pass without comment.

"It is unnecessary," said J. W. Stephens, "to devote sole attention to pools, to miasms, to breeding places, etc., the *Anopheles* itself might be disregarded, but the attention of the physician should be exclusively concentrated on the "*infected Anopheles.*" We are, as a body, only beginning to teach the lesson that malaria is a contagious disease, and that, for the tropics at least, the native population, particularly the child population, carries the organism in the blood, and frequently without showing any signs of its presence. It is this apparently healthy but highly infected population which is the great source of malarial parasites, and the great danger. Of the methods of prophylaxis, four deserve special mention. These measures are antilarval, mechanical use of wire netting, quinine prophylaxis and segregation.

The antilarval method is fundamental and if thorough drainage can be effected, it is sufficient, but economically it often assumes such stupendous proportions as to be impracticable. As a system of sanitary reform, however, it should be carried onward as a steady continuous policy. Petroleum sprinkling is a temporary makeshift; the water removal should be made the nucleus of the attack.

Mechanical prophylaxis by wire netting has been demonstrated to be very highly efficient, both by the Italians, and by the Japanese in their recent war procedures. They have shown the remarkable results that in a particular regiment the malarial patients diminished from 2,000 in 1900 to 256 in the first six months of 1903. It is said that even the sentries wore veils and gloves at night.

Quinine prophylaxis is attended with success, if we are to accept the opinions of many that discussed the question. The German investigators claim results from the use of fifteen grains of quinine repeated on two consecutive days, and it seems certain that quinine *per se* is not a cause, of the so-called blackwater fever.

Segregation of the infected individual is the most logical of the recent methods of prophylaxis. This is a procedure comparatively easy in operation, although at times it may cause a great amount of discomfort.

Such is the outline of the results arrived at in this recent discussion. Should its lessons be taken to heart, we may hope for a still further reduction in the mortality of malarial fever in this country.

PUERPERAL ECLAMPSIA AND RECENT PROGRESS.

The mystery of the causation of eclampsia has always remained one of the alluring problems to which obstetricians in every generation have applied themselves. Its recent discussion at the American Medical Association in the Section on Medicine (see Society Proceedings in the Medical News, p. 1223, June 25, 1904) shows that it still remains a baffling mystery, although some new light has been thrown on its etiology and perhaps also on its treatment.

The most important feature of the discussion was the emphasis laid on the fact that so-called eclampsia undoubtedly consists of more than one type of pathological process and indeed probably represents a group of affections of very various nature and very differing significance. There seems to be no doubt that in certain cases of so-called eclamptic convulsions there is nothing more than a set of reflex convulsive attacks, brought about in highly neurotic individuals by intense irritation of important nerve endings within the abdomen. It is comparatively easy to understand that as convulsions occur in children as the result of a reflex irritation due to the cutting of teeth, so in older persons of unstable nervous equilibrium, corresponding convulsive seizures may take place. It is by no means absolutely necessary that the patient should have previously exhibited a marked neurotic disposition. Pregnancy is a condition that easily lends itself to the bringing about of an irritable condition of the nervous system.

There seems no doubt that in certain individuals so-called eclamptic convulsions must be considered to be frankly hysterical in origin. When eclampsia develops shortly before or just after the birth of the child and is limited to one or two seizures without any serious preliminary symptoms and without important after-effects, it is not unlikely that in many cases the convulsive attack is of a true hysterical character. Anyone who has seen hysterical convulsions, particularly certain of the cataleptic seizures of major hysteria, will not be surprised that such attacks should, in the midst of the excitement of labor, be considered to be eclamptic. It is possible for such a seizure to occur without there having been any very telltale symptoms of hysteria beforehand, although usually there will be found to be a distinct family heredity of neurotic disposition. Some of the many and various remedies which at different times have been recommended as positively curative for this always annoying complication (their name is legion) undoubtedly owe their reputation to their apparently successful employment in cases of this kind. While the condition may for the moment seem very serious it has all the favorable prognosis that a neurotic condition always has and there are no complications or sequelæ likely to do permanent harm to the patient.

On the other hand, the failure of practically all methods of treatment in certain severer cases of eclampsia shows that the true nature of this affection has not yet been discovered, and that the theories of causation so far advanced are probably incomplete. It used to be considered that patients who exhibited a large amount of albumin during the course of their pregnancy were very likely to have eclamptic seizures. Obstetricians of large experience tell, however, that they have frequently followed such patients carefully, keeping them under the most minute observation, in order to avoid accidents, and have failed to see any symptoms of eclampsia develop. In fact, it has come to be generally recognized now that it is not large amounts of albumin in the urine, but instead small, but persistently present, quantities of albumin, which may be followed by a true eclamptic attack, or a series of them. For a time also it was thought that eclampsia always meant that renal insufficiency had been present for some time with a consequent accumulation of excrementitious material in the system. Careful observation has shown that the estimation of the urates and uric acid over long periods does not give any sure indication as to the probable occurrence of an eclamptic attack and that even a marked reduction in the total solids excreted, while it may serve to indicate the approach of nephritic symptoms, does not necessarily signify the approach of eclampsia. Anuria has been known to occur with death in coma without ever a symptom that might be called eclamptic.

Certain of the fatal cases of eclampsia seem to be due to an increase of pressure within the skull. This is usually the result of edema of the brain, which may be caused by the kidney insufficiency of nephritis. Just why some cases present the tendency for edema of the brain to

occur while others do not, remains one of the mysteries of individual peculiarity. At the recent meeting at Atlantic City, Dr. Robert N. Willson, of Philadelphia, presented some cases in which the diminution of intracranial pressure by means of lumbar puncture brought with it distinct relief from symptoms. It did not, however, cure the patient, and in all of them a distinct amount of edema of the brain was found to be present post mortem.

In the discussion aroused the possible connection between acute yellow atrophy of the liver, the pernicious vomiting of pregnancy, and eclamptic seizures was suggested. Recent post mortem observation has shown that in all of these conditions a specific and characteristic degeneration of the liver cells is present. In the most advanced stages this constitutes the so-called typical acute yellow atrophy. In less advanced cases, lesions that evidently represent initial stages of this same pathological condition are present. How serious some of them are may be best appreciated from the severity of the clinical symptoms, pernicious vomiting and eclampsia, with which they seem to be directly connected in the relation of cause and effect. Investigation along this line of observation may lead to the discovery of the true pathological basis of these severer conditions which has so far been very obscure. Such cases are rare enough even in hospital practice, and as the lesions spoken of are characteristic and comparatively easy of recognition, it would seem that practitioners of medicine anywhere throughout the country who have opportunities to make autopsies on such cases should not miss the occasion to add their quota of information on this important subject.

PROLONGATION OF CONVALESCENCE.

Three years ago the medical world was surprised by a declaration of Sir William Broadbent, in a discussion of typhoid fever at the annual meeting of the British Medical Association that convalescence from typhoid fever should last for at least a year and in many cases longer. It is easy to understand that so serious an illness as typhoid fever and one which so frequently calls for the exercise of all the resistive vitality of the patient, needs more than the scant month or two, that is sometimes allowed for recuperation. On the other hand, there are very few physicians notwithstanding the authority of Sir William Broadbent, who would consider that more than three months is necessary before a patient, who has recovered from typhoid fever, may be allowed to go back to his former occupation.

At the recent meeting of the American Medical Association, at Atlantic City, this question of prolonged convalescence after typhoid fever as well as after other infectious fevers, came up in the discussion on arteriosclerosis. As we approach our maximum incidence of the disease in the autumn months, it seems well to recall the purport of that discussion. There was a unanimous belief expressed that it is especially on the circulatory system that the toxins of infectious disease are likely to produce their most serious and enduring effect. Unfortunately when there is question of strain upon the circulatory system, the heart is usually considered to be the only element likely to be seriously affected and the arteries are apt to be neglected. At the end of typhoid fever all patients are warned of the absolute necessity of not sitting up suddenly in bed. The practice of gradually raising the head of the bed so as to accustom the heart once more to pumping against the force of gravity, has become widespread. As a consequence of these precautions sudden death at the beginning of convalescence from typhoid fever are rarer than they used to be.

However, the other dynamic factor in the circulation, the arteries, are usually not treated with so much consideration. When arteries lose their elasticity it is well known that the heart must do double work. The active contraction of the arteries is quite as important for the continuance of the circulation as the heart itself. It is also known that the heart suffers to such a degree from the toxins of infectious disease that a certain amount of fatty degeneration is almost the rule. This takes place in the muscular coat and it seems not unlikely that the same structure in the artery suffers if not to the same degree at least to some extent. The arteries recover more slowly than the heart, because their blood supply is not so abundant and their nutritional processes not so rapid.

Hence the necessity for prolonged convalescence after a continued fever, such as typhoid. Dr. William S. Thayer, of Baltimore, pointed out that in very many cases of arteriosclerosis typhoid fever is one of the features of the patient's history. In his observations there is only one other infectious disease, rheumatism, and this has of course an acknowledged reputation for producing serious effects upon the circulatory

system, that is noted more frequently in previous histories of arteriosclerosis patients than typhoid fever. His statistics seem to furnish a clinical demonstration of the theoretical and pathological considerations which have been advanced as emphasizing the necessity for prolonged convalescence.

Of course it will not be easy to persuade the busy men and women of our generation that a year to eighteen months should be given solely to more perfect recuperation when they have already been kept from their occupations for some six to ten weeks during the course of the disease itself. But medical insistence will find many arguments to influence them. The most interesting feature of the results produced by modern progress in medicine is the increase of the length of average life. Five years, at least, has been added to the length of a human generation in the last half century. The too strenuous life is, perhaps, the most serious factor in opposition to further progress in the same line. The overzealous worker must be taught the important lesson that the gain of a few months just now may mean the loss of many vigorous years a little later in life.

At the present time too many people are carried off by any serious illness that attacks them after the age of forty-five. Usually, in these cases, where there is not some distinct organic affection, a degeneration of arteries is at the bottom of their lack of resistive vitality. The persuasion that this is frequently due to infectious disease and the neglect of sufficient convalescence therefrom is now very common among clinicians of large experience. There is opportunity for a distinct improvement in medical practice that will save not a little of after-suffering and incidentally prolong life.

Typhoid fever, of course, is not the only affection the sequelæ of which are to be feared. There is no doubt in the minds of many conservative clinicians that the modern coal-tar treatment of rheumatism, by freeing patients from pain sooner than formerly, has been one reason for more frequent permanent heart crippling and arterial degeneration after rheumatic fever. After the so-called ordinary diseases of childhood the tendency of parents is to send children back to school just as soon as permission can be obtained for them to return, that is to say, as soon as the Board of Health considers that they are no longer in danger of spreading the disease. This practice is undoubtedly fraught with no little risk to the child's developing organism and to prevent it the family physician should demand a longer period of convalescence. If this were done we should hear much less of measles and whooping-cough as a predisposing cause of tuberculosis. In fact the resistive vitality of young patients is so much lowered by these so-called trivial diseases, that a subsequent infection, which ordinarily would be thrown off readily, finds favorable soil for growth. There is in this important matter of the prolongation of convalescence a special field for the family physician and the general practitioner of medicine that cannot fail to be fruitful of good for this and future generations.

ECHOES AND NEWS.

NEW YORK.

Reception to Visitors at Academy.—Next Thursday evening, October 6, 1904, a general reception will be held at which many distinguished foreign confrères will be present. The profession of the city are cordially invited to attend and to extend their welcome to our colleagues from foreign lands.

Columbia University.—The following is the list of the newly appointed professors in the medical department: Gorham Bacon, M.D., Professor of Otology; Joseph A. Blake, M.D., Professor of Surgery; George E. Brewer, M.D., Professor of Clinical Surgery; James R. Hayden, M.D., Professor of Genito-Urinary Diseases; Arnold Knapp, M.D., Professor of Ophtholmology; Samuel W. Lambert, M.D., Professor of Applied Therapeutics; Harry McMahon Painter, M.D., Profesor of Clinical Obstetrics; Frederick Peterson, M.D., Clinical Professor of Psychiatry; William K. Simpson, M.D., Professor of Laryngology, and John S. Thacher, M.D., Professor of Clinical Medicine.

The following appointments of adjunct professors are also announced: Frederick R. Bailey, M.D., Adjunct Profesor of Normal Histology; Eugene Hodenpyl, M.D., Adjunct Professor of Pathological Anatomy; Russell Burton-Opitz, M.D., Adjunct Professor of Physiology, and Francis Carter Wood, M.D., Adjunct Professor of Clinical Pathology. On Saturday, October 8, a reception by the President to the new appointees will be held in Earl Hall, from four until six o'clock.

The Eastern Medical Society.—The first open meeting for the season of the Genito-Urinary Section of this society will be held on Tuesday, October 4, at 8 P.M., at Clinton Hall. The paper of the evening will be "Ureteral Catheterization, with Special Reference to the Treatment of Pyelonephritis Catarrhalis," by Dr. Winfield Ayres. Discussion by Drs. W. J. Pulley, Follen Cabot, Frederick Bierhoff, Ferd. C. Valentine and possibly others. Cases will also be presented.

Dr. Lederle on Food Adulteration. Dr. Ernst T. Lederle, who is at present in Germany, prepared a paper on the above subject for the International Congress of Arts and Sciences at St. Louis. It was in part as follows: "An important field is now opening to the sanitarian in the investigation of manufactured food products. The extent to which

commercial adulteration and substitution is now practised would be absolutely incomprehensible to the layman. Competition in trade has become so keen and the substitution of inferior constituents in foods so general that the honest manufacturer has hardly a chance to succeed. The use of injurious preservatives has also been practiced to a scandalous extent. The only remedy for this evil condition will be the passage and enforcement of a Federal pure food law. Such a measure has already been before Congress, but in the absence of an aroused public opinion, the mysterious influences which bar the way of much good legislation at Washington have been able to kill it. Much the same opportunity is offered in a campaign against the vendor of patent medicines and secret nostrums. Few people understand the extent to which these articles undermine the public health, and there has been little or no attempt to assume official control over their production and sale. The remedy is official control. Makers of patent medicines, nostrums, pills, etc., should be required to place upon each bottle or packet the exact ingredients it contains, and should be prosecuted for any deviation which can be shown to be detrimental to the health of persons using the remedy, or designed to perpetrate upon them a commercial fraud."

The University and Bellevue Medical School.—The following new appointments for the University and Bellevue Hospital Medical College are announced for the coming year: Dr. George P. Wallace, to be Assistant Professor of Pharmacology; Dr. Herman A. Haubold, to be Clinical Professor of Surgery. A lectureship on pathological chemistry, recently endowed by Dr. Herter, has been awarded for the present year to Dr. Phœbus A. Levene, of the Pathological Institute on Ward's Island. The enrollment of the entering class of the Medical School is more than twenty per cent. larger than it was on the same date last year. Immediately upon the completion of the new medical laboratories, a part of the present Carnegie Laboratory will be set apart for a students' library and reading room.

PHILADELPHIA.

Smallpox Hospital Closed.—The smallpox building at the Municipal Hospital has been closed for the first time in five years, no new cases having been received for four weeks. Director Martin considers the return of the disease as a remote possibility, chiefly because of the house-to-house vaccination kept up during the summer by the medical inspectors. This is to be continued indefinitely.

To Suppress Smoke Nuisance.—The smoke nuisance ordinance goes into effect October 1, and preparations have been made to enforce its provisions. A report has been made on each of the 5,991 buildings possessing steam equipment, specifying if hard or soft coal is used and if smoke-consuming devices are employed.

Addresses by Foreign Physicians.—On Friday, September 30, the students and faculty of Jefferson College were addressed by Dr. Lauder Brunton, F.R.S., formerly lecturer on Therapeutics in St. Bartholemew's Hospital, London, and Prof. Dr. Oscar Liebreich, Professor of Pharmacology in the University of Berlin.

Almshouse Bids to be Readvertised.—Director Martin has requested Director of Public Safety Smyth to readvertise for bids on the new Almshouse, the old specifications calling for a building inadequate for the needs of the city. The plans, prepared under a former administration, are to be materially changed. Councils are also to be asked to change its name from the Home for the Indigent to the Home for the Aged and Infirm.

Jail for Sellers of Impure Milk.—Five milkmen, convicted for selling adulterated or watered milk, have been fined by Judge Barrett from $50 to $75, and sentenced to jail for periods varying from ten to twenty-five days. The grand jury has found indictments against 27 men for selling adulterated Hamburg steak. Food Commissioner Warren is highly pleased with the way the courts are dealing with the men apprehended by his department.

Pathological Society.—The Philadelphia Pathological Society held its first meeting for the season on September 22. Dr. D. J. McCarthy showed specimens of tumors of the choroid plexus and discussed their nature and histology. Drs. David Riesman and A. G. Ellis exhibited specimens consisting of a primary carcinoma of the stomach with secondary extension to the liver and pancreas. Officers for the ensuing year were nominated.

No Exhibits at the Pittsburg Meeting.—At the meeting of the Medical Society of the State of Pennsylvania, held at Pittsburg, September 27 to 29, the usual custom of having an exhibition of books, instruments, drugs, etc., was dispensed with. This was believed to detract nothing from the interest of the meeting as the pharmaceutical exhibit was always composed largely of patent remedy compounds.

Discussion on the Purification of Water.—At the meeting last week of the Franklin Institute, the subject for discussion was "The Use of Copper Sulphate as a Germicide for the Purification of Potable Water." John W. Hill, Chief of the Bureau of Filtration, made the statement that the water as it will be supplied the city after the completion of the filtration plant will be absolutely pure and will not need the addition of copper sulphate to render it free from typhoid bacilli. Director Martin said that the Department of Public Health, in doing what it had toward the use of copper sulphate, was striving for the purification of the water now being served. He is a firm believer in filtrated water but does not advocate sitting quietly by and letting the scourge of typhoid continue while the filters are being completed. The experiments in the laboratory are for the benefit of Philadelphians until they are served with pure filtered water. Most of the speakers agreed that the use of copper sulphate in far greater quantities than are recommended for purifying the water would be harmless to the general population.

The Care of the Insane.—The Association of Superintendents and Trustees of Institutions for the Insane in Pennsylvania held a meeting at the South Mountain Asylum on September 22. The meeting was the largest ever held, the attendance being 28. The inspection of the buildings and grounds and the condition of the 800 insane was a revelation to many of the members. Almost every inmate partly supports himself by labor on the farm in connection with the institution. Papers at the meeting were read by Drs. Robert H. Chase and J. M. Murdoch. Officers elected are: President, Dr. John B. Chapin, Philadelphia; Vice-President, Dr. H. B. Meredith, Danville; Secretary, Dr. M. S. Guth, Warren. The next meeting will be held at Polk, in May, 1905.

Positions at the University.—The position of assistant in bacteriology in the Laboratory of Hygiene, University of Pennsylvania, and the Thomas A. Scott Fellowship in Hygiene in the same laboratory, are vacant for the year 1904-1905. Further information may be obtained from the director of the laboratory.

CHICAGO.

Shorten the Time from the Cow to the Baby; a Plea for Twelve-Hour Milk.—Commissioner of Health, Dr. Arthur R. Reynolds, of this city, presented a paper on this subject before the Section of Public Health of the International Congress of Arts and Sciences, at St. Louis. In introducing the topic, Dr. Reynolds said that State laws and city ordinances prescribed requirements for dairies, milch cows and the constituents of their milk and cream offered for sale. It had been stated, he said, that Chicago could get milk within twelve hours from the time of milking, but that it was usually twenty-four or thirty-six hours old before delivery. The thirty-six-hour old milk was held to be positively harmful to the young in all cases where the milk was not bottled, but shipped in bulk. Dr. Reynolds continued: "Old milk not only starves the young, but it poisons them, causing diarrhea, 'summer complaint,' etc., and the excessive mortality among the young—especially during hot weather, which hastens souring of milk by favoring the growth of the bacteria. Milk is the principal article of diet for children after they are weaned until they are four or five years old. It is the sole article of diet for infants who cannot be nursed by their mothers. Milk, in the diet of adults, does not fill so important a place. Old milk or poor milk may be used for coffee and for table use generally by adults without any great harm, for the quantity used at any time is small compared to their total diet. All milk intended for the use of children should be bottled in the country, immediately after having been thoroughly cooled. The bottles should be put in cases, packed with broken ice, and so shipped to consumers within twelve hours after bottling, and at a temperature below 50 degrees. Milk bottled in the city cannot rank with the country-bottled milk, because it is shipped to the city in cans without being iced, and because after the cream has risen during the transit the butter fat cannot again, without the greatest pains, be thoroughly intermingled with the milk so that each bottles receives its due proportion. Nor are the producing dairies, as a rule, under the rigid supervision that is insisted upon by those who bottle in the country.

Milk Supply of Chicago.—To sum up the most important results of personal investigation of a number of dairy farms from which Chicago receives its milk supply: (1) An increasing proportion of Chicago's milk is delivered to the consumer within twelve hours after milking. The bulk of it, however, is from twenty-four to thirty-six hours old before delivery. There is no insuperable reason why it should not all be delivered within the shorter period, and every effort of the department is being made to this end. (2) There is much room for improvement in the condition of milk production on nearly all the dairy farms visited, except those under the direct supervision of a few large contracting firms. The dairy inspectors of the department are engaged in visiting this class of farms, explaining to their owners the necessary requirements, reporting upon their conditions, and recommending the exclusion of their product from the Chicago market if, after a reasonable time, they fail to conform to these requirments. (3) It costs more to produce clean milk than dirty milk—therefore cheap milk is, prima facie, impure and unwholesome milk, and the housekeeper who buys it is helping to perpetuate unclean conditions of dairies and helping to swell the death rate of the city by having her babies die off from disease caused by stale and impure milk. The consumer should make it an object to the milk producer and the milk dealer to furnish a clean, fresh and wholesome product, by being willing to pay a fair price for such product and by giving personal attention to its quality and proper care after its receipt.

P. and S. Lengthens its Course.—It has been announced that the College of Physicians and Surgeons (Medical Department of the University of Illinois) will extend its course to nine months. The term opened September 27, 1904.

CANADA.

Montreal General Hospital.—At the regular quarterly meeting of the Board of Governors of the Montreal General Hospital, held last week, it was decided to alter the constitution so as to leave the Medical Board free to engage the officers of the resident medical staff from outside of the British Dominions. The constitution now provides that no person shall be eligible for one of the positions of resident medical officer unless he is a graduate or licentiate in medicine in some university or college approved by the Medical Board. Formerly the clause of the constitution was to the effect that the physician must be a graduate or a licentiate of some university or college in "British Dominions." The receipts for the past quarter were $16,071, and the expenditure $21,521. Two donations were received during the quarter, one of $2,000 and the other of $5,000. Dr. J. Alex. Hutchinson read the medical report. During the quarter there had been in residence 781 patients. Of this number 67 died, but 26 of these died within three days of their admission, which would leave the ordinary mortality rate of 5.5 per cent. In the outdoor department there were 9,072 consultations as compared with 8,651 for the corresponding quarter of the previous year.

The Care of Inebriates in Ontario.—On September 19, there was held a meeting at Government House, presided over by the Premier of the Province, the Hon. George W. Ross, for the purpose of discussing the best plans for the care and treatment of the inebriate. Dr. A. M. Roseburgh, of Toronto, who has taken a deep interest in this subject for the past decade, delivered an address setting forth what had been done in the province toward this end, and he was followed by Dr. T. D. Crothers, of Hartford, Conn., who outlined a system for the care and treatment of inebriates. At the conclusion of his address, Professor McPhedran, of Toronto University, moved a resolution to the effect that the time was now ripe for the formation of a society for the reform if inebriates. A committee was organized for the purpose of organizing a society and another meeting will be held at a near date for the purpose of arranging a constitution and completing the regular organization of the new society.

McGill's Medical Faculty Opens for the Season.—Last week McGill Medical Faculty reopened for the session 1904-1905, when there was present Professor Abbott, of the University of Pennsylvania, to deliver the opening address. Dr. Abbott took for his

subject "The Study of Medicine and Recent Advances in Medical Science." Dr. Roddick, Dean of the Faculty, who has just returned from England, announced that while abroad he had interviewed Lord Strathcona, who had promised to contribute $50,000 toward the general purposes of the Medical Faculty of McGill. Regret was expressed at the approaching departure of Dr. Tait McKenzie, who will shortly take up his duties in connection with the University of Pennsylvania.

Canadian Medical Protective Association.—This Association was organized at the Winnepeg meeting of the Canadian Medical Association in 1901, with Dr. R. W. Powell, of Ottawa, as President. According to the third annual report just issued, it has a membership of 288, of which number Ontario makes up 217 and the balance distributed over all of the provinces with the exception of Prince Edward Island, which has not a single member. It is a most worthy organization and deserves the liberal support of the Canadian medical profession. At the recent annual meeting, held at the conclusion of the Canadian Medical Association, the constitution was changed to provide for a more practical and efficient management.

Dominion Registration.—Owing to the fact that the legislature of the Province of Quebec failed to ratify the necessary amendments to the medical laws of that province, the accomplishment of Dominion Registration has not up to the present time been arranged. The question was taken up again at the recent meeting of the Canadian Medical Association, and a strong resolution passed favoring the memorializing of the Quebec Government, the Quebec College of Physicians and Surgeons, as well as educating the medical profession in the province of Quebec, through the lay press, to the advantages of such a measure. It was further advised that Dr. Roddick, M.P., who has taken such a deep interest in the movement, should have at his command a special committee of three prominent and influential members of the Association in each province, for the purpose of exerting their influence upon the Quebec legislature to pass the necessary legislation as will make this most desired Roddick Bill or the Canada Medical Act, valid and effectual.

The Question of Patent Medicines at the Canadian Medical Association.—Dr. C. J. Fagan, of Victoria, B. C., read a timely and important paper at the recent meeting of the Canadian Medical Association at Vancouver. Having heard same the Association appointed Dr. Fagan as chairman of a Special Committee to bring in a resolution on the subject. This was done and it was recommended in same that the Canadian Medical Association should bring the matter to the attention of the Federal Government that the latter should take immediate steps to thoroughly investigate the nature and contents of all patent preparations on the market and to suppress the dangerous and harmful literature, all of which is deemed most prejudicial to the health of the community. The resolution carried unanimously and the matter will be laid before the Federal authorities at an early date.

Personal Items.—Dr. T. F. Underhill, of Vancouver, has been appointed health officer of that city.

Sir Lauder Brunton has been the guest of Professor McPhedran at Toronto, during the past week.

Dr. Charles O'Reilly, medical superintendent of the Toronto General Hospital, has been elected vice-president of the Association of Hospital Superintendents.

Dr. Breffney O'Reilly, only son of Dr. Charles O'Reilly, of Toronto, has gone to Vancouver to assume his duties on the C.P.R.S. Tartar.

The Medical Faculty of Toronto University reopens on October 4.

Dr. M. K. Church, of Merrickville, Ont., is dead at the age of seventy-six years.

The Winnepeg General Hospital has received a donation of $500 from Mr. F. W. Thompson, of Montreal.

The Provincial Royal Jubilee Hospital of Victoria, B. C., treated 144 patients during the month of August.

The Vancouver General Hospital has appointed an active staff of twelve practitioners and a consulting staff of five.

GENERAL.

Foreign Appointments.—Professor Lorrain Smith, of Belfast, and Dr. A. S. Grünbaum, of Liverpool, have been appointed to chairs of pathology, respectively, at the Universities of Manchester and Leeds.

Maryland School Bequest.—The courts have confirmed the bequest of $40,000 made by the late Dr. William H. Crim to the University of Maryland School of Medicine.

A New Library for Cooper Medical College.—The Cooper Medical College, of San Francisco, has received a bequest from Mrs. Pauline C. Lane, wife of the late Dr. C. L. Lane, which enables it to build a library.

Lane Lectures.—Dr. William H. Welch, of the Johns Hopkins University, has given the Lane lectures at the Cooper Medical College, San Francisco, his subject being "Infection and Immunity."

Dartmouth Medical School.—Among the new appointments are Dr. Percy Bartlett, A.B., Bowdoin, '92; M.D., Dartmouth, 1900; instructor in anatomy; Dr. C. C. Stewart, Pennsylvania, assistant professor of physiology; Dr. John O. Polak, lecturer at New York Post Graduate School and Long Island College Hospital, assistant lecturer on obstetrics.

Boston Items.—The addition to the Stillman Infirmary for an infectious ward is well under way; and in Boston the foundations have been put in for the new Medical School buildings of Harvard University.

Naval Medical School.—The Naval Medical School in Washington, began its regular course of instruction on September 30, with twenty student officers in attendance. The faculty of the school will be the same as last year, with the exception of Medical Director John W. Ross, who is on duty with the Panama Canal Commission. His place will be filled by Surgeon P. A. Lovering, who was recently detached from duty on the Asiatic station.

Officers American Academy of Ophthalmology.—At the Denver meeting of the American Academy of Ophthalmology and Oto-Laryngology, held August 24, 25 and 26, 1904, the following officers were elected: President, Dr. H. W. Loeb, of St. Louis, Mo.; First Vice-President, Dr. D. T. Vail, of Cincinnati, Ohio; Second Vice-President, Dr. Robert Levy, of Denver, Col.; Third Vice-President, Dr. Eugene Smith, of Detroit, Mich.; Secretary, Dr. Geo. F. Suker, of Akron, Ohio; Treasurer, Dr. Otto J. Stein, of Chicago; Councils, Dr. H. W. Loeb, Edw. Jackson, W. L. Ballenger, Casey A. Good, J. M. Ray, of Louisville. The next place of meeting will be decided upon by the Council and will be announced shortly.

Resolutions Concerning Death of Dr. Steinberger.—WHEREAS, We feel that in the untimely demise of our esteemed coworker, Dr. Victor Steinberger, we have lost a genial companion, an arduous worker, a progressive physician and an earnest and sincere colleague, therefore be it

Resolved, That we medical inspectors and trained nurses of the Department of Health, of the City of New York, Borough of Manhattan, at a special meeting held July 23, 1904, extend to his widow and to his family our heartfelt sympathy in the hour of their bereavement. May the remembrance of his affable personality, his conscientiousness in his duties, his devotion to his beloved ones and his uprightness of character serve to lighten their grief, to strengthen them in their affliction and be a blessed memory in the future. And be it furthermore

Resolved, That these resolutions, suitably engrossed, be presented to his widow and that a copy be published in the City Medical Journals. Jacob Sobel, M.D., Edward M. Thompson, M.D., E. Helen Knight, M.D., Otto A. Jahn, M.D., L. Marcus, M.D., Henry J. Blumensohn, M.D., and Thomas W. Neapsey, M.D., *Committee*.

Southern Medicine and Gaillard's Medical Journal, beginning with the October issue, are to constitute a consolidated journal. In negotiating the purchase of *Gaillard's Medical Journal* the editor of *Southern Medicine* has not been actuated solely by a desire to enlarge the subscription, though he does not claim to have been unmindful of the many advantages accruing from such an accretion. In 1897 the present editor of *Southern Medicine* established the *Georgia Journal of Medicine and Surgery*. On the first of January, 1904, *Southern Medicine* was thought to be a more appropriate name. *Gaillard's Medical Journal* was established at Richmond, Va., in 1886, by Dr. E. C. Gaillard, a Charlestonian, and a graduate, in 1854, of the State Medical College of South Carolina. Dr. Gaillard was a prominent surgeon in the Confederacy, and *Gaillard's Medical Journal* has always been considered a Southern journal, though for many years past it has been published in New York City. The records of both journals show them to have been harmonious in their aims and methods, and it is most fitting, therefore, that they should combine their several interests and resources to further those aims and improve those methods to the higher upbuilding of American medicine, and furthering the interests of the whole medical profession.

Professorship Fees in Germany.—According to the *Evening Post* the financial considerations involved in the calling of prominent men from one of the German universities to another are rarely made known. It is, however, reported semi-officially from Vienna that Prof. A. von Eiselberg of that university, called to succeed the famous surgeon König in Berlin, was offered a salary of 32,000 marks and guaranteed 25,000 marks in lecture fees. For family reasons, however, he declined this brilliant offer.

The Study of Medicine in Germany.—We learn from the *Evening Post* that a remarkable document has been sent by the executive committee of the National Medical Association to the 482 gymnasia and 131 Realschulen of the empire, with an urgent request for distribution among the graduates. It is an official appeal *not* to enter upon the study of medicine. The chief reason is the deplorable financial condition of an exceedingly large percentage of physicians. The determining facts adduced are (1) a surplus of medical men much beyond the demand; (2) the abrogation of the laws against practise by the incompetent; (3) legislation for the Krankenkasse. The increase in the number of physicians has been enormous, from 17,728 in 1876 to 24,225 in 1887 and 29,133 in 1902. The number has more than doubled in a single generation, and the prospects are that the "learned proletariat" in this department will grow still more in the next year, since women and the graduates of the semi-classical Realgymnasia are now admitted to the profession. A further reason for avoiding this study as given by the circular letter is the fact that the addition of a "practical" year to the course has made the expenses of preparation, already very costly, still more so.

International Medical Congress.—The fifteenth International Medical Congress will convene in the last week in April, 1906, in Lisbon. The preliminary program arranges for fifteen sections. The official language of the convention will be the French, but German and English will also be permitted in both the general meetings and in the sections.

Governmental Monopoly of Opium.—Entirely commendable is the action of the commission appointed by Secretary Taft in recommending control of the supply and sale of opium by the Philippine Government. This conclusion was arrived at after complete and careful study of the use and abuse of opium in Japan, China, Java, Formosa, and the Straits Settlements. The commission states that the use of opium in the Philippines does not at this time constitute as grave a social danger as it does in China and other neighboring countries, and on that account it is all the more important to stamp out the evil if possible, or to check it and restrain it within bounds. The Filipinos are becoming addicted to the use of the drug through its importation by the Chinese, 70,000 of whom are making every effort to propagate their nefarious business in the islands. In considering how best to control and check this traffic the commission considered five methods of action: High license, local option, farming, prohibition, and a monopoly, and decided that the last named was the practical way of dealing with the evil. All of these methods have been tried in the various countries visited by the commission and have been found wanting, the monopoly, however, in a less degree than any of the others. In Spain the farming system has been used solely for revenue purposes, a procedure which the United States does not consider justifiable from any standpoint. As for prohibition, its attempt among an Oriental people, many of whom are Chinese, would be quite as useless as is the effort among certain Occidentals to control the use of alcoholic beverages,—simply to encourage the evasion and transgression of unwise laws. The proposed registration and licensing of chronic opium smokers ought to have a decided deterrent effect on those who have not yet become habitués, realizing how hopeless these are, in so far as radical methods of treatment go on so vast a scale as would be required. As a corrective and educative measure all Filipino opium habitués are to be deprived of the right of franchise, and to be ineligible for any public office, municipal, provincial, and insular. Gratuitous treatment of all habitués wishing to free themselves from the opium vice is to be provided in the hospitals at Government expense. The method seems entirely rational and, in the light of knowledge and expediency, is the only fairly reasonable way of coping with the great curse of the far East.

Study Room and Book Psychology.—We quote with sympathetic feelings an editorial from our distinguished contemporary, the *Evening Post*. Speaking of the type of "Chair Sociologists," an apparently rampant type, they say: "The proper study of mankind is never without its enthusiastic votaries. Of late years, however, it has taken on more and more the sta-

tistical form. The philosopher of to-day has scant sympathy with such an idea as Emerson's, that every man carries in hieroglyphic the answer to those inquiries he would put. The inquiries the modern man would put he thinks to get answered by hunting up two hundred specific cases, classifying them, and concluding that truth lies with the division having the numerical preponderance," which, may it be interpolated, they label the "Normal Man." "It was in this wise that a pedagogical expert, if we recall the feat correctly, conducted experiments in the development of the artistic sense. After testing some thousands of infants with some hundreds of pictures, he announced to the world the surprising conclusion that young children preferred colored pictures to black and white. The Pauline maxim, "Prove all things," is, in this sense, of proving what everybody knew before, sadly overworked. We have heard, for example, the story of a prominent professor, an authority on child study, whose youthful son, reared though he was in accordance with the latest discoveries, proceeded to bombard a dinner guest with buttered biscuits. The first missile the guest received in silence, seeing that the family paid no attention to the occurrence. When the second caught him on the spotless shirt bosom, however, he opened his mouth to protest, but was interrupted by his hostess, who held up a warning finger, saying, "Hush, the professor is observing him in his wrath." From our inner consciousness, and such exhibitions as have come incidentally under our notice, most of us know, or think we know, what a person does when he is angry. But the careful scientist notes that he throws buttered biscuits. He would delight to compare this observation later with the case of another person who hurled a plate of soup. A Beloit College professor is the latest example of seeking wisdom in numbers. He has spent the summer pushing a wheeled chair over the St. Louis fair grounds, and from that "favorable viewpoint" studying the crowds and individuals there to be seen on parade. Sociology is the most wonderful of sciences, as we all know, but the question at once arises, "Why is the back of a wheeled chair an especially favorable place for studying it?" The investigator who lives for six months in a Bowery lodging house, spends the summer as a tramp, or digs in the subway, can at least say that he had a chance to know and observe people whom he would not have known and observed had he stayed at home. He can write a book about these people. Sometimes he can make it a very interesting book. The Beloit professor, however, has no such advantage. He has been observing all summer the backs of the necks of people whose faces he might have gazed upon if he had been strolling about the grounds wearing a silk hat and swinging a cane. It is hard to escape the conclusion that he could have studied them even better that way. When wheeling a most uninteresting subject, he may see a "type" full of suggestion, just turning the corner. He would follow if he were free, but in his menial station he must go on propelling the dull and humdrum while the exceptional slips away. Then, in any case, the people at the fair do not constitute a class or social group. They are a little of everything. Probably a hundred or so come from Beloit, and the professor could have scrutinized them from his study window. Students of the St. Louis crowds have already made one observation which really throws light on human nature. They have found a brisk demand for rented crutches among sound and sturdy men who are ashamed to let themselves be seen in a wheeled chair unless they display some ocular proofs of infirmity. That fact was first noted not by a trained observer, but by an ordinary pedestrian with no special mission. If our chair-wheeling psychologist makes other discoveries of equal value his summer will be well spent. Yet we cannot put away visions of the statistical method. "Of a half-hundred visitors who were charged five cents for a drink of ice water, exactly fifty manifested indignation." That has the merit of infinite pains to prove a useless fact which everybody might have known beforehand. Or we might get a better index to the crowd's mental condition from reading, "Of 817 persons who were shown Minnesota's butter statue of Father Hennepin discovering the Falls of St. Anthony, 43 showed pleasure, 112 evinced symptoms of actual dislike, while 662 were apparently affected in no way whatever."

OBITUARY.

Prof. Dr. Niels Finsen, the noted therapeutist, died September 24, 1904, at Copenhagen. Dr. Niels Finsen came into public notice for his discovery of a light cure for lupus, or tuberculosis of the skin, and other skin troubles. It has been known for a long time that sunlight is beneficial in such complaints. Finsen sought for the principle which makes sunlight fatal to germs, hoping to provide a cure which would operate on cloudy days and would intensify the properties of sunlight. He declared that he had found this principle in the violet and ultraviolet rays. He perfected an electric apparatus which shut out all other rays but these. With it was combined a most ingenious cooling apparatus. The Finsen rays have more than justified the faith of their discoverer in the treatment of lupus, but in other lines the results have not been encouraging. On the strength of his discoveries Dr. Finsen received the Nobel prize in 1903. This prize is given every year to the person who has done the greatest work for the advancement of mankind.

Dr. John J. Mackey, a well-known Brooklyn physician, died last week at his home at Bergen Beach, after a protracted illness. He was born in Dublin, Ireland, and when sixteen years old he entered the Medical School of the Dublin Catholic University, coming to this country a few years later with his parents. He was graduated from the Bellevue Medical College.

Dr. George S. Conant, fifty-one years old, died at his home, No. 148 East Eighteenth street, New York. He had been a sufferer from diabetes for many years. Dr. Conant was a graduate of the Bellevue Medical College.

Dr. John Purcell, eighty-six years old, died at Larchmont, September 26, at the home of his daughter, Mrs. Dowdney. Dr. Purcell was born in Ireland, and was for thirty years a well-known physician of New York City.

Remarks on Adenoid Vegetations.—Swelling of the cervical lymph glands is frequently the result of a disease in the pharyngeal tonsils, and it is not essential that both conditions should be due to scrofula. W. Lublinski (*Berl. klin. Woch.*, July 11, 1904) calls attention to the fact that the enlargement of the pharyngeal tonsil need not be so far advanced as to produce mechanical obstruction, but even a moderate degree of proliferation may call forth symptoms. These consist especially of extension of inflammatory processes into neighboring organs, such as the palatal tonsils, ears, eye and nose, which cannot be accounted for on mechanical grounds alone. Mention is also made of the chronic, constantly recurring form of cough, which accompanies adenoid vegetations and which he thinks is due to the dropping down into the larynx of secretions. Continuous febrile conditions are also associated with this condition.

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Seventeenth Annual Meeting, held at St. Louis, September 13, 14, 15 and 16, 1904.

The President, Walter B. Dorsett, M.D., in the Chair.

Address of Welcome, on behalf of the St. Louis Obstetrical and Gynecological Society, was delivered by Louis E. Newman.

David R. Francis, President of the Louisiana Purchase Exposition, followed the remarks of Dr. Newman by an interesting and instructive address.

Responses to these addresses of welcome were made by Dr. L. H. Dunning, of Indianapolis, Ind., and Dr. Herman E. Hyde, of Buffalo, N. Y.

Operative Treatment for Painful Menstruation in Young Virgins.—A paper with this title was read by Dr. William A. B. Sellman, of Baltimore, Md. The author pointed out the great necessity of giving relief to young unmarried women who suffered from painful menstruation. The means employed should not be of a character to unsex the patient or prevent her from bearing children or from fulfilling her marital relations. The operation should not be one which will endanger life or interfere with the woman's general good health. To illustrate the condition and to demonstrate the manner in which cases could be operated upon without unsexing the individual, and giving absolute relief from the suffering experienced, the author related a case upon which he operated the early part of June, 1904. The patient, Miss H., aged twenty-four years, a brilliant vocalist with a register of three octaves, had been unable to use her voice with any satisfaction for a long period on account of the pain developed in the ovarian region when attacking the high notes. June 7, 1904, under ether anesthesia, the author curetted the endometrium, removing a quantity of congested tissue from the cavity of the uterus. He then made an abdominal incision in the median line, and found both ovaries hyperemic and distended. Upon the left side he opened three good-sized cysts and upon the right side two medium-sized cysts. The Graafian follicles in each ovary were distended. He enucleated these with a sharp spoon curette, and scraped the walls of the cysts in order to destroy the germinal membrane. He then closed these openings with catgut sutures and used the same material with which to close the opening in the abdominal wall. The patient made an uninterrupted and rapid convalescence, and had not had the slightest amount of pain in the ovarian region, and no pain during the menstruations which she had passed through, since the operation. He thought very many gynecologists would have removed both ovaries under these conditions, and the result would have been the unsexing of the patient and probably the loss of her voice, especially in the upper register. Her voice had not been impaired in the slightest degree by the operation. The author showed three sizes of reamers devised by himself, which he had used for ten years in overcoming the condition of stenosis or obstruction where every other means failed. In not a single instance, when handled properly, had he witnessed any injury inflicted by them.

Dr. Herman E. Hayd, of Buffalo, New York, alluded to the importance of examination of these cases, and said even after an examination was made one might find that the most distressing cases were the ones that practically had no evident pathology. On a previous occasion, the speaker said, he read a paper on this subject in which he pointed out that retrodeviation of the uterus was responsible for much of the dysmenorrhea in unmarried women. If one upon examination should find a retroverted uterus, a prolapse ovary, a tender, sensitive tube, then there was a rational basis on which to work, but simply because a woman had a small os it did not follow that she was going to be the subject of dysmenorrhea, because it all probability most of these cases were simply due to an impoverished condition of the whole system. They were simply functional troubles, and had to be met accordingly. If, however, there was an obstructive dysmenorrhea, where there was a pinhole os, and usually these cases were associated with a congenital atrophic condition of the uterus, the small undeveloped uterus, probably one could institute some operative measures, and the interference which had been most successful in his hands had been dilation and the wearing of a stem pessary.

Dr. William H. Humiston, of Cleveland, Ohio, stated that dysmenorrhea was a common disturbance, and yet he had been unable to find a case that was not accompanied by an inflammatory condition of the mucosa. He had seen cases of narrow, conical os, with the patients menstruating without the least sign of distress, but the moment there was an inflammatory condition of the mucosa added to that, that moment the patients began to have painful menstruation. In cases of this kind he thoroughly dilated the uterine cavity, curetted, and had the patients wear an Etheridge pessary, closely watching them for several months, and if there was no accompanying disease of the appendages, the cure was decided and complete. But in these cases occasionally one would have a failure because he did not recognize an ovary which was smaller than normal, the cirrhotic ovary, which was hard to detect unless an examination was made under an anesthetic, and there was no relief afforded except the removal of these shriveled, corrugated, smaller than normal, ovaries.

Dr. D. Tod Gilliam, of Columbus, Ohio, spoke of the undeveloped condition of the uterus as a cause of dysmenorrhea. A great many men had come to the conclusion that it was not a superficial condition; it was not produced by the condition of the uterine mucosa, as a rule; it was not the result of stenosis of the internal os, but was due to the undeveloped, unripe condition of the uterine tissues.

Dr. Sellman, in closing the discussion, stated that he did not use his instruments in all cases, but only in a certain class. He would not use them in a case in which the dysmenorrhea was brought about by an inflammatory condition, but only in those cases where a gristly condition existed.

Pseudomembranous Monocystic Tuberculous Peritonitis.—Dr. H. W. Longyear, of Detroit, Mich., in a paper with this title, after defining this condition, reported three cases of the affection, and stated that the treatment consisted of abdominal section, with evacuation of fluid and the thorough washing out of all shreds and gelatinous masses with normal salt solution; thorough drainage by glass or rubber tubes, both abdominal and vaginal. This was to be followed by after-treatment consisting of frequent lavage, with a weak aqueous solution of iodine (tincture iodine, 1 dram; water, oi), until the pseudomembrane was disintegrated and the purulent discharge which followed had ceased. Internally, the rational treatment of tuberculosis, consisting of the use of creosote, cod-liver oil, etc., a supporting diet, and suitable hygienic surroundings. The prognosis was bad, al-

though a few cases might recover, if not too far advanced, after months of constant drainage and careful nursing.

Chronic Adhesive Peritoneal Sclerosis.—Dr. N. Stone Scott, of Cleveland, Ohio, stated that among the rarer abnormal conditions found within the abdomen, was one particularly interesting, and possibly more frequent than had hithertofore been suspected. This condition was progressive, yet was characterized by an absence of active symptoms, including ascites. In the early stages the peritoneum was rigid and contracted; later the connective tissue became excessively hypertrophied, with adhesions between the involved peritoneum and all viscera with which it came in contact. As soon as these adhesions interfered with the functions of any organ, symptoms referable to such interference supervened. When the involvement prevented some important organ from performing its necessary functions, death ensued. In an illustrative case cited by the author, only a circumscribed portion of the pelvic peritoneum was affected.

Relative Value of the Means and Methods Employed in Accouchement Force.—Dr. E. Gustav Zinke, of Cincinnati, Ohio, read a paper with this title, in which, after epitomizing the various views gleaned from the literature of the subject, he drew the following conclusions: (1) The graduated steel or vulcanite dilators and the ordinary branched or bladed dilators were mainly employed for the purpose of dilating the cervix or os preparatory to digital manual and bag dilatation. (2) The bag or hydrostatic dilators, of which the Champetier de Ribes balloon and its modifications were the most favored, should be employed only when time was not an important element in the case; when the cervix was thoroughly softened, partly or entirely effaced, and an easy introduction of the balloon possible. This form of hystereurysis was contraindicated in central placenta previa, and in eclampsia, mild or severe. If, in these cases, it was determined to empty the uterus, deep cervical incisions, vaginal or abdominal hysterectomy, promised the best results for mother and child. To prevent continuation of the cervical incision, a suture might be placed in the upper angle of the wound. (3) The manual dilatation of Harris and the bimanual (digital) dilatation of Bonnaire and Edgar. A soft and partially obliterated cervix and dilatable os were absolute prerequisites for this variety of uterine dilatation. It was to be preferred to hydrostatic hystereurysis when time constituted an important element. Under this method the life of the fetus was often lost and, unless great care was observed, sepsis, lacerations, hemorrhage, profound shock and sometimes even death of the mother might occur. (4) Deep cervical incisions and Duhrssen's vaginal hysterotomy were destined to play a permanent and important rôle in the management of forced labors in the future. Many of the cases now subjected to manual or balloon dilatation would be treated by cervical incisions. It was the method in the presence of sepsis of the vagina, because the operation was short in duration and could be performed under a continuous flow of an antiseptic solution. An intact cervix, whether hard, elongated or not, was always an indication for cervical incision. Vaginal hysterotomy was indicated principally when the cervix was the site of malignancy or extensive cicatrization. If there were a palpable difference between passage and passenger, the conservative Cæsarean section should be the choice of operation. (5) The indications for the conservative Cæsarean section had been so well defined by himself here and in previous papers, that it was needless to repeat them. Cervical incisions and Duhrssen's operation would, however, take its place in many instances, notably in cases of marked prematurity. (6) The Bossi and similar metal dilators, if they were not entirely needless, they were certainly very dangerous instruments. From what had been said, it was safe to predict that rapid and complete metal dilatation would never become a popular method; that sooner or later it would receive universal condemnation and thus reach its final and well-deserved destination—the lumber room of obstetrical instruments.

Dr. Henry Schwarz, of St. Louis, was glad to hear the author's experience with reference to Duhrssen's vaginal Cæsarean section, because personally he had had no experience with that method. He fully agreed with all that Dr. Zinke had said, except that he (Dr. Zinke) appeared to be too radical in some respects. He could conceive of exceptional cases of eclamptic convulsions or of placenta previa, in which Cæsarean section might be justifiable in proper hands and under proper surroundings. As a rule, in eclamptic convulsions Duhrssen's method should be the one of choice, and there could be very few exceptions where conservative Cæsarean section was indicated. As to Bossi's dilator, it had a limited sphere of usefulness. He had used it successfully in one case.

Dr. James F. W. Ross, of Toronto, Ont., said he had done Cæsarean section three times, with the recovery of the mother in each case, and the loss of the child in each case. He gave reasons why the children were lost in these cases. The question between Cæsarean section and the Porro operation was pretty well settled, and the conclusion had been reached that the latter, when Cæsarean section failed, enabled one to control hemorrhage. He had operated on two cases of rupture of the uterus, with recovery in both instances, after having performed the Porro operation, using gauze packing, and he thought this operation in these cases should not be adopted except for uncontrollable hemorrhage.

Dr. J. Henry Carstens, of Detroit, Mich., emphasized the point that many practitioners were too anxious to dilate the cervix in the class of cases under discussion. He had seen them use rubber dilators and dilators of all kinds in working around the uterus, for two or three days at intervals, and then finally had to send for some one to help them out of difficulty, or they had to call in counsel. It was a mistake to suppose that because a woman had a little pain at the approach of labor that she was actually in labor.

Dr. Zinke, in closing the discussion, said that whatever he may have said or written in the past on this subject and presented to-day came from a motive simply to do good in the future, and to get rid of a certain method of practice in obstetrics which had been the means of rendering families unhappy, and because he honestly believed that there was great room for improvement in this practice in spite of all that had been said against it.

Vaginal Cæsarean Section in Grave Cases of Puerperal Eclampsia.—Dr. J. Henry Carstens, of Detroit, Mich., said that mild cases of puerperal convulsions could be ordinarily controlled by the treatment generally advocated for this class of cases, but there was a serious grave form of puerperal eclampsia where one convulsion followed another in quick succession, and the patient finally died in spite of ordinary, and sometimes even heroic, treatment used.

This severe variety of eclampsia could generally be subdued by immediate delivery. This was accomplished generally by manual dilatation, the use of powerful steel instruments, like that of Bossi, but what was better still was the operation called vaginal Cæsarean section, which enabled the obstetrician to deliver the woman in about five minutes with little or no danger. In conclusion, he stated that (1) in grave puerperal eclampsia, as a rule, prompt delivery will save the patients. (2) That manual effort with the fingers and the hand was too slow. (3) Powerful steel dilators were not always at hand, and often caused serious injuries. (4) Vaginal Cæsarean section enabled the obstetrician to quickly and safely deliver the woman.

An Unusual Case With Many of the Symptoms of Appendicitis.—Dr. Magnus A. Tate, of Cincinnati, Ohio, narrated this case. The patient, a boy, aged seven years, was attended by Dr. L. Linss, of Cincinnati, for an ordinary attack of scarlet fever, from February 25 to March 18, 1904. March 21, Dr. Linss was called to see the boy on account of a swelling of feet and hands. On the morning of April 1, all edema had disappeared; urine highly colored, but normal in quantity, with no sugar, albumin or casts. That afternoon the patient had a chill, vomited and was suffering with a pain in the abdomen; temperature 99.5°. Pulse 90. April 5, the patient had two more attacks of vomiting; pain in the abdomen was constant, and he had not slept for twenty-four hours; temperature 102° F. and pulse 130. Dr. Wm. Johnson saw the case with Dr. Linss, and upon examination of the abdomen they found an uneven swelling which extended to the umbilicus, and over the right lumbar region. Upon palpation exquisite tenderness over the appendix was elicited. A diagnosis of appendicitis was made, but further consultation was asked for. The next day, April 6, Dr. Tate was called. When he saw the patient, six days after the initial vomiting spell and chill, the child had been crying and moaning day and night, and could not sleep; temperature 102° F.; pulse 132; very irregular; abdomen swollen, especially on the right side, and such marked tenderness that the child screamed if the slightest pressure was made over the region of the appendix. Bowels constipated and the urine highly colored. The following day there was no improvement, the pulse even worse; temperature remained at 102° F. Before placing the child on the operating table, a bed-pan was placed under him and he passed nearly a pint of urine. Chloroform was administered, and an incision was made on the right side two inches in length, over the most prominent portion of the swelling. It revealed a dark-colored sac and a number of adhesions. The incision was lengthened to three inches; some adhesions were broken down with the finger, but a few of them were so firm that they had to be cut. The enlarged opening gave a field of about two inches to work in, and the sac in appearance was not unlike that of a gangrenous bowel. They were at a loss to say exactly what it was, and as adhesions limited the field, gauze was packed about the opening, the child turned to the right side, and a half-inch cut was made into the sac. A dark-green fluid spurted out, which had a strong heavy odor of stale urine. About two quarts of fluid was evacuated, and the finger introduced into the sac, which proved to be the bladder. The opening in the bladder was sewed up, adhesions binding the bladder on to the abdominal wall and on the right side to the large and small intestines were broken up, and the enlarged thick-walled bladder dropped back into the abdominal cavity. The appendix and appendical region, except for the presence of some adhesions, were normal. An opening was left in the abdomen for gauze drainage, and the rest of the wound closed up. The subsequent history was that the bladder was emptied by means of a retention catheter for forty-eight hours; after that catheterization night and morning for three days. There was a gradual decrease in pulse and temperature, and in seven days both were normal. On the third day a quantity of fluid drained out through the opening, but this gradually ceased, and on April 23, sixteen days after operation, the abdominal wound had closed, and the patient was now in good health.

Gunshot Wound of the Abdomen.—Dr. John D. S. Davis, of Birmingham, Ala., reported a case of gunshot wound of the abdomen, with eighteen perforations, in which he resorted to intestinal resection of five feet, seven inches, with use of metal button, followed by recovery of the patient. The patient, a woman, twenty-three years of age, while attempting to place a rifle in the rack on the wall, the gun was discharged with the muzzle about eight inches from the abdomen. The bullet, a 32 caliber, entered in the median line midway between the umbilicus and the symphysis pubis, ranging backward, upward and to the right, and was deposited in the muscles of the back on the right side. The ball in traversing the abdomen, made eighteen perforations of the gut, and two cuts in the intestine that went to the mucous membrane. Sixteen of the perforations and the two sero-muscular wounds were in the small intestine, and two pertorations in the transverse colon. The bullet cut two mesenteric arteries which caused a large amount of blood to collect in the abdomen. Patient was shot at 4:30 o'clock in the afternoon, February 2, 1904, and was brought a distance of eighty miles on a freight train to Birmingham, by her physician, Dr. W. O. Watson, and carried to Hillman Hospital. At nine o'clock the essayist saw the patient and had her prepared for section. Temperature at this time was 102° F., and pulse 130. She probably had fever at the time she was shot. A seven-inch incision was made in the median line, a large quantity of blood turned out, and the bleeding vessels controlled by hemostatic forceps. The two perforations in the transverse colon were so near the mesenteric border that he stripped up the mesenteric serosa and turned the mesenteric border in as though the two openings, one on each side, had been one large opening, including mesenteric border, and closed with interrupted silk sutures. He then brought the mesenteric folds back and sutured over the wound. Four perforations and two sero-muscular cuts in the small intestines were turned in and closed with small loop silk sutures. Two perporations were situated so close together that they had to be closed by flexing, pouching or looping the mesenteric border, the bowel being bent on its convexity so the two wounds could be closed as one large wound by interrupted longitudinal loop sutures,—suture with axis of bowel. There were two other perforations that could not have been closed by suture, but the openings were between the mesenteric perforations on one side, and eight on the other, and he thought it better to lose one more foot of intestine than to do two resections. He resected that part of the intestine containing the ten mesenteric perforations (67 inches), including the two large perforations in the convexity of the ileum and closed with the third sized metal button. The resected bowel and its mesentery were removed, the vessels

ligated, and the gap in the mesentery closed with interrupted silk sutures. The abdomen was flushed with hot normal salt solution; plain gauze drainage was used, and the abdomen closed with through and through silkworm-gut sutures. The operation lasted one hour and a half. Drainage was removed on the second day. Patient passed the button on the twenty-first day, and left the hospital March 1, 1904. A week later she was doing housework, and was now perfectly well. Dr. Davis also exhibited the metal button which was made in four sizes, like the Murphy button, with the exception that it had no spring. In his opinion, the spring served no good purpose, was an additional expense, and made the button more difficult to apply.

He also showed a metal horseshoe button which he had made to take the place of his catgut horseshoe plates, which he had been in the habit of using to close large wounds on the convexity of the bowel without destroying the mesenteric border by resection.

Clinical Reasons for Advising Early Operations in Fibroid Tumor of the Uterus.—Dr. Rufus B. Hall, of Cincinnati, Ohio, discussed this subject under three heads: (1) Which cases should we advise not to be operated? (2) In which cases should we advise late operations? (3) In which cases should we advise early operations?

The author discussed at some length the clinical history of patients in order to form a correct conclusion.

1. If a patient between thirty-five and thirty-eight years of age, suffering from a fibroid tumor of the uterus, the tumor and uterus combined making a mass not larger than a cocoanut, had no symptoms other than profuse metrorrhagia, the whole period not extending over five or six days, and she was free from pain except at her menstrual periods, it would be wise and judicious not to interfere surgically. But this patient, during her entire menstrual life, should be considered an invalid by her physician and should report to him at once if her symptoms became aggravated.

2. If she suffered pain in one or both iliac regions at other times than at her menstrual periods, the cause of the pain should be discovered at once and corrected. On the contrary, if her menstrual period was prolonged to ten or twelve days, the loss of blood amounting almost to a hemorrhage, and this hemorrhage could not be controlled or mitigated by the usual internal medication, and rest during the period, the advisability of an operation should be considered.

3. Prolonged and severe uterine hemorrhage had not been considered a sufficient reason for advising an operation. A patient suffering from a tumor as large or larger than a cocoanut, who had profuse bleeding at each menstrual period and the period was prolonged for eight, ten or fifteen days, as it frequently was, was in considerable danger. It was the author's experience that a large majority of those patients in whom the hemorrhage could not be controlled by medicinal remedies in two weeks, came to operation sooner or later. They could frequently stand off the operation two or three weeks, or in some instances longer, but the anemia was profound, and if some complication arose in the tumor, ovaries or tubes, making an immediate operation necessary, they were in the worst possible condition for it. The chances for a successful operation were greatly diminished. Therefore, when the hemorrhage could not be controlled within a few months, these patients should be advised to have the operation made before the anemia was pronounced. These symptoms, however, were not of so much importance as others, but if permitted to continue for many months they caused profound anemia and lowered vitality, and a high mortality followed the operation. He regarded hematoma, complicating these tumors, as the gravest complication the surgeon had to deal with in the management of the late cases. His records showed that only one patient in seven operated upon for fibroid tumors, where pus tubes were present, developed peritonitis after the operation; while five in every six of those operated upon in which hematoma of the ovary existed, suffered from peritonitis following the operation for removal of the tumor. The speaker had notes of one case of a woman suffering from a fibroid tumor about the size of a cocoanut, who ceased to menstruate at forty-seven and all symptoms attributed to the tumor disappeared. He removed the tumor when she was thirty-six years old, after it had been causing trouble for six months, and it had malignant disease well advanced in it. Other similar cases were cited. His experience in removing these malignant fibroid tumors had been that within a year or two after the operation for removal of the tumor, the patient had a recurrence of malignant disease in the pelvis and abdomen, and succumbed within a few months.

Shall We Remove All Fibromata of the Uterus on Diagnosis?—Dr. Thomas B. Eastman, of Indianapolis, Ind., read a paper with this title. After quoting freely numerous writers on the subject of the removal of fibroid tumors, the author stated that in the 117 cases upon which he had operated for fibroid tumor of the uterus, complications which bade fair to result eventually in death were encountered in 43 cases. Hydrosalpinx, either unilateral or bilateral, five times; suppurating dermoid cyst, three times; sarcoma, once; parovarian cyst, once; necrosis of tumor, eight times; cystic degeneration of ovaries, three times; ovarian cyst, four times; intraligamentous development of fibroid, three times; pyosalpinx or salpingitis, seven times; hematosalpinx, once; cystic degeneration of the tumor, once; myxomatous degeneration, three times; adeno-carcinoma of body of uterus, twice. Among the more prominent complications, appendicitis was encountered once. In addition to the complications inherent in the uterus and its adnexa proper, there were those arising from the pressure of the mass upon the bladder, rectum, ureters, and the persistent anemia resulting from prolonged hemorrhages. In the writer's 43 complicated cases, as well as in those of other writers on this subject, it was a significant fact that those complications which were inherent in the tumor, and which presaged the most certainly fatal results, were those of such character as to preclude a positive knowledge or ofttimes even a suspicion of their existence prior to operation or even a microscopical examination. This, then, was the arraignment of the uterine fibromyoma, and in the mind of the author justified their removal in all cases, except in so few as to scarcely merit attention. Should not all fibromata be removed upon diagnosis, not for the harm they were now doing, but against the harm that they might do in the future? As far as the danger was concerned, the removal of a fibroma was attended with as little danger as the average abdominal section, and he was not unmindful that the removal of the uterus from a comparatively young woman was not a thing to be lightly considered. The results obtained by various operators warranted

one in classing it among the safe operations, the mortality being in the hands of skilled men scarcely more than five per cent., a mortality certainly much less than would result from the policy of procrastination, which advocated delay until the forces of death plus those of the operation outweighed those of surgical interference. There was nothing so innocent as an innocent fibroid, and nothing so treacherous. When one considered the dangerous conditions into which an innocent fibroid might quickly change itself, and the ease and safety to the patient with which this innocent fibroid might be removed, the writer believed that the deduction was evident that all fibroid tumors of the uterus should be removed upon diagnosis.

Removal of Skeleton of Ectopic Fetus, Ulcerating Into Bladder, by Vaginal Cystotomy.—Dr. William D. Haggard, of Nashville, Tenn., reported the case of a white woman, aged thirty-one years, the mother of two children, who presumed herself to be normally pregnant and expected to be confined August 30, 1900. There was a continuous flow from the uterus for the first three months, and she had pain in the bladder and straining on micturition from the beginning of conception; but there was no history of rupture of the ectopic gestation. On June 20, at six and a half months, while lying down, she felt motion for the last time. Previously it had been unusually vigorous, more so than with her two other children. She was confined to her bed for three or four weeks with pain. She had more or less pain for about a year and she was a semi-invalid from weakness, pain and tenderness in lower abdomen. The enlargement of the abdomen had gradually, but appreciably, diminished. At the end of a year, pus first made its appearance in the urine, and the first day after getting up a bone, which was a fetal vertebra, made its exit through the urethra. During the second year she had been able to attend to all household duties, but occasionally would have several days of unusual bladder irritation, and pass a bone through the urethra. In the last four months she had passed all the long bones. Sometimes one would catch in the urethra. She would get hold of the free end and gradually pull it out. Commonly several days of comparative comfort would elapse before another one would set up irritation, and finally escape. In this way she passed eighty-five bones. Six weeks before admission to the Infirmary she felt the discomfort of another bone, and had not been free from it since, nor had any bone passed. She had been in bed two weeks with pain in the lower abdomen, which was very intense on motion.

Upon examination, the bladder was exquisitely tender, crepitated upon pressure. Bones were covered with phosphatic deposit. She described a small lump to the right of the median line and low down, the remains of the once six and a half months' enlargement, but this could not be made out on account of tenderness. The urine was loaded with pus and phosphates, and exceedingly offensiveness. Curiously enough, the woman did not void it oftener than every six or eight hours. Micturition was very painful and after the urine was voided, free pus was often expressed.

Under ether, October 31, 1902, the index finger was made to enter the urethra without much effort, and detected numerous bones, and communicating with the bladder, an opening into a lesser chamber on its right upper surface. There was a mass on the right to be made out bimanually, about as big as a small orange, and communicated with the bladder much as a bow window with partially drawn curtains did with a room. The uterus was retroverted and not much enlarged. The bones were much too large to be removed through the urethra, and an incision was made into the vesicovaginal septum. The finger in the bladder through the urethra located the bone, and it was withdrawn with a forceps introduced through the incision. In this way fifty-two bones were removed. Some were embedded in granulation tissue in the remains of the ectopic sac, and were with difficulty removed. The sac and bladder were freely irrigated, and an artificial vesicovaginal fistula established for drainage, after Emmet's method of sewing the vaginal mucosa to that of the bladder by silver-wire sutures.

The operation, while tedious, was not attended with shock. The bladder was irrigated twice daily afterward with boric acid solution, and the urine soon became normal. At the end of six weeks the artificial vesicovaginal fistula was closed successfully by silver-wire sutures. A cystoscopic examination with the Bransford-Lewis uretercystoscope revealed a healthy mucosa, and at the site of the former communication, only a slight reddish depression was seen. The ureteral catheter failed to disclose any depth to this aperture, and the patient was discharged eight weeks after the operation, and has remained well since.

Presidential Address.—Dr. Walter B. Dorsett, of St. Louis, Mo., President of the Association, stated that in casting about for a subject upon which to address the Fellows, he had for consideration the various operations for the relief of retrodeviation of the uterus. He spoke of the excellent operative work which had been accomplished within the past few years, so that what he had to say was more of a resumé of what had been done surgically. He discussed the methods of operation, saying that the different plans of accomplishing the reposition of the uterus might be classified according to the route selected by the advocates of each. They might be divided into extraperitoneal, vaginal, and intra-abdominal. After considering and discussing exhaustively the different methods in vogue, and indulging in some criticism of them, he stated that some of the methods did not merit the prominence they had obtained in the estimation of the profession at large, and for the reason that no one could arrive at a proper conclusion as to the best method of relieving the suffering woman without a careful study of the different methods. If one operation was in accord with the accepted idea of proper surgical technic, the other certainly was not. When one considered the great diversity of opinion as to which was right and which was not, without a proper appreciation of them all, one was certainly at a loss as to the choice of operations. In his opinion one should not consider any operation that did not contemplate the possibility of a thorough inspection of the adnexa from above the pubic bone. He would discard the entire class of operations that contemplated vaginal incision, either anteriorly or posteriorly, on account of the greater liability of sepsis as well as from the impossibility of anchorage to firm structures. While ventrosuspensions and ventrofixations had been condemned as unjustifiable, he took it that it was because only the fixation or suspension that was accomplished by anteverting the uterus and stitching the fundus, or, perchance, the posterior uterine wall to the abdominal wall, had been considered. It was reasonable to assume that this unnatural suspension or fixation was a causative factor in the production of lengthened adhesion bands for the entanglement of bowel as well as barrier to the proper development of the pregnant uterus. If, how-

ever, a lower segment of the anterior uterine wall was attached lower down on the abdominal wall, and omentum was allowed to drop to or behind the uterine fundus, the bugbears of necessary Cæsarean sections in labor cases and entangled bowel would be less feared. His own work in obstetrics and with this operation justified him in this statement.

Gunshot Wound in the Hip-Joint.—Dr. L. H. Laidley, of St. Louis, reported a case of gunshot wound of the hip-joint, but before doing so referred to the literature of the subject. The patient, aged eighteen years, a visitor and looker-on, of remarkably vigorous constitution and unexceptional health, was shot in a brawl on "The Pike" at the Exposition, on June 18. He was admitted to the Emergency Hospital, and within one hour an abdominal section was made. Upon examination, it was found that the ball had passed through the abdominal wall near McBurney's point, passing inward and slightly downward. On examining the viscera it was found that the ball had penetrated the cecum, making two openings, one in front and behind, passing down into the soft parts into the pelvis. These were closed by Lembert sutures, the abdomen cleansed of large quantities of blood and escaping contents of the bowel, and the abdomen closed with through-and-through sutures. The patient left the table within an hour under very favorable circumstances, the pulse being 72, temperature normal. The next morning he complained of great pain in the hip-joint, and was unable to move that limb. For ten days his condition was favorable, when he gave evidence of disturbance, especially about the joint. Chills and fever and increased pain suggested an examination with the X-ray, which would have been used earlier were it not for the fact that they had not been provided with such an appliance up to that time. On July 11, after the bullet was removed, an incision was made over the joint, disclosing the presence of pus outside of the joint, which was opened, showing that all of the head of the bone within the capsule was entirely destroyed and fractured; the acetabulum was likewise fractured and necrosed; following up the course of the cavity made by the bullet, the missile was removed, having lodged in the upper and outer margin of the cavity of the socket. The necrosed portions of this bone was chiseled out, and with a sharp curette were entirely leeansed, the dead portion of the head of the femur was also removed, the cavity packed with gauze and thoroughly drained. He afterward showed evidences of sepsis, which prompted the author on July 22, to reopen the wound, washing out the cavity, and introducing further drains. These were continually used up to the present time. About three weeks ago, the patient manifested evidence of acute nephritis. Upon examination it was found that he had a large quantity of albumin, with casts, which was evidently due to toxemia as found in scarlet fever. Since that time, by repeated cleansing of the cavity and thorough drainage, these evidences were disappearing, leaving the patient in a fair condition for recovery. The subsequent treatment would be to free the cavity and its surrounding structures of all suppuration, and by this means the author hoped to restore his patient to his normal health, probably leaving him with a shortening of the limb and perchance a degree of anchylosis. The patient was exhibited.

Strangulated Umbilical Hernia.—Dr. John Young Brown, of St. Louis, reported an interesting case of complicated strangulated umbilical hernia, and presented the patient.

Sterility Due to Retrodeviation of the Uterus and Its Treatment.—Dr. Herman E. Hayd, of Buffalo, N. Y., read a paper on this subject, in which he reported twelve pregnancies following the simple Alexander operation. Among other things, he stated that posterior displacements of the uterus were a very frequent cause of sterility. Pregnancy had frequently followed when such a uterus was placed in position, either by pessary or operative measures. He made an eloquent plea for the simple Alexander operation for a large class of suffering women who had simple uncomplicated retroposed uteri. In reporting the twelve cases in which pregnancy followed the simple Alexander operation, it was pointed out that the ligaments had stood the test of pregnancy and parturition. The canal was never opened *per se;* the internal ring and peritoneal cavity under no circumstances whatsoever. The author made a plea that the simple Alexander operation should be always employed for this special class of sufferers, in whom a pessary was not worn with comfort or willingly tolerated.

A Unique Case of Circumscribed Infection of the Placenta and Excessive Vomiting, the Cervix Uteri and Ovum Being Intact.—Dr. Albert Goldspohn, of Chicago, reported this case. There was a first pregnancy of three to four months with severe nausea, and much vomiting, almost from the beginning, with the gradual additional development of fever, and finally also severe chills and a scanty, foul discharge. There was no alteration in the shape and consistency of the cervix, or of the body of the pregnant uterus. The patient had a rapid pulse, and irregular, high temperature, and chills. The uterus was emptied. The membranes and ovum were intact. The edge of the placenta bore a circumscribed area of broken-down gelatinous tissue, with a very offensive odor. The author gave a brief review of the current views of the pathology of hyperemesis gravidarum and considered the rare etiological bearing of the above case.

Conservation of the Natural Resistance of the Patient in Surgical Work.—Dr. Robert T. Morris, of New York, in discussing this subject, said that the late Lawson Tait, was the first great exponent for conservation of the natural resisting force of the patient. Tait operated very quickly. He did as little as possible. He avoided handling viscera; he avoided disturbing the patient's mind with details of what he was about to do. He treated the most difficult case lightly, and patients looked at it in the same light. The repair of surgical injury depended primarily, secondarily and finally upon a proper hyperleucocytosis. The author used this term in a generic way to avoid elaboration of detail in statement. This was a manufacturing process carried on under the control and guidance of the sympathetic ganglia. The more the surgeon shocked a patient, the more he lessened the production of the leucocytes. The common ways for lessening the natural resistance of the patient were prolonged anesthesia, and unnecessary amount of anesthetic. All surgeons had seen patients who had been literally drenched with ether; they had seen patients carried to the danger line with chloroform. On the other hand, surgeons had watched the beautiful work of men who were expert in giving anesthetics, who began with nitrous oxide and a little oxygen, then changing to ether, who did it skillfully, quickly, nicely, and avoided shock which took away one element of resistance from the patient. Quick work was a point in which Tait excelled. Expeditious work conserved the natural resistance of the patient. Undoubtedly the resistance of patients was lessened in abdominal surgery with gauze packing. He said that if ten healthy policemen were taken from the street and a yard of gauze was introduced into the peritoneal cavity, those policemen the next day would not be in good condition. This being so, how could one expect a patient with septic appendicitis to be in good condition if a yard of gauze was

packed into the abdomen. If one drained quickly, got out of the abdomen quickly, disturbed the bowels as little as possible, made short incisions—in other words, leaving the patient alone as nearly as possible—he would make such a wonderful recovery that one might be accused of taking out a normal appendix. The tendency was to do too much.

If a surgeon pricked his finger in operating on a septic case, the surgeon died, while the patient recovered. Why was this? The patient was loaded with bacteria and toxins. The patient had called out all of his resistance factors; his hyperleucocytosis was under way ready to meet infection and bacteria. The surgeon had not called out his resistance factors, hence the bacteria proliferated rapidly and gained ascendancy. Was it necessary for the surgeon to get all of the septic culture media out of the patient's abdomen? No. All he needed to do was to turn the scale; there was a conflict between the bacteria and the leucocytes in that patient's case; the bacteria were winning; the leucocytes were losing. What did the surgeon do? By taking out most of the toxins and bacteria quickly, he turned the scale, turned the balance in favor of the leucocytes, and they went on and won. He took unfair advantage of them, but if he had labored conscientiously in accordance with text-books, and the best authorities, he would have put the patient out of commission where he should not have done it.

Officers for the Ensuing Year.—The following officers were elected for the ensuing year: President, Dr. H. W. Longyear, of Detroit, Mich.; Vice-Presidents, Dr. D. Tod Gilliam, of Columbus, Ohio, and Dr. John Young Brown, of St. Louis, Mo.; Secretary, Dr. Wm. Warren Potter, of Buffalo, N. Y., re-elected; Treasurer, Dr. X. O. Werder, of Pittsburg, Pa., re-elected; Councillors, Dr. James F. W. Ross, of Toronto, Ont., and Dr. Walter B. Dorsett, of St. Louis.

After the introduction and adoption of resolutions of thanks, the Association adjourned, to meet in New York City in 1905, the time to be fixed by the Executive Council.

NEW YORK ACADEMY OF MEDICINE.

Section on Genito-Urinary Diseases.

Stated Meeting, held May 18, 1904.

The President, James Pedersen, M.D., in the Chair.

(Continued from Page 624.)

Report of a Case of Suprapubic Bladder-Valve in a Case of Inoperable Carcinoma of the Prostate.—Dr. Ramon Guiteras reported the case of a man, sixty years old, who suffered from some stomach trouble for five years. He had had days when he vomited, was nauseated, had bad taste in his mouth, dizzy feelings, etc. He had no appetite and his sense of taste was lost, his bowels were constipated, he had pain in his back for weeks, and lost 15 pounds. He was placed upon suitable diet and his stomach treated with various medicines. After a few visits he disappeared. Six months ago he returned saying that when his stomach trouble returned he would take medicine and diet himself and he would then be better. In another month he had another return of his stomach trouble and complained of sour stomach, nausea and flatulency. Then he had pain in the back, diarrhea, desire to urinate five or six times during both day and night, and this was accompanied by pain and spasm. The pain and urinary symptoms kept up until the day of his visit. The abdominal examination was negative. The prostate was enlarged, indurated and extended to the right side. The urine was yellow, specific gravity 1,025, acid in reaction, no albumin, a few red blood cells, some pus and a few hyaline and granular casts. The residual urine was about two ounces. One or two weeks after there was incomplete retention, suprapubic pain, tenesmus and dribbling. Examination at the office showed sixteen ounces residual urine. The patient then went to some local physician who catheterized him three times a day. The residual urine decreased to six ounces and he was able to pass spontaneously three pints in twenty-four hours. A suprapubic cystotomy was performed and when the bladder was opened there was found a mass in the right side of the abdomen and the bladder wall infiltrated and it was evident that the growth could not be removed and, therefore, a Gibson operation was performed. A 33 Fr. catheter passed into the bladder and the fascia and skin was stitched around the tube. A No. 2 chromic silk was used for the upper layer and a No. 2 chromic for the floor and ordinary gut was used for the skin. Convalescence was uneventful. A catheter was tied in the urethra. It was two months before the valve seemed sufficient to permit the patient urinating through his urethra without leakage through the suprapubic opening, and during this time it was necessary to resort to a number of methods in order to see if he could not make the valve hold. The valve would not hold until it admitted a catheter not larger than a 15 Fr. The valve at this time was two and one-third inches in depth. Two months after he left the hospital and four months after the operation he voided seven or eight ounces of urine without leakage, but there was a residual urine of 12 ounces. Occasionally his bladder was washed out with nitrate of silver solution and kept on urinary antiseptics. Five months after the operation the patient died of an intercurrent pneumonia. The case was interesting to him at that time—six months ago—because he had another patient who appeared with symptoms similar to the one reported. In both cases there was a prostate affected with carcinoma and the prostates were about the same size. In each case he advised the introduction of the suprapubic valve because the growths were inoperable ones. In one instance the patient was operated upon, the prostate removed and the patient died within a few days. The other patient had the valve introduced and lived five months after the operation and then died of pneumonia. His experience in these two cases, coming on about the same time, led him to the conclusion that in cases of extensive malignant disease of the prostate it was better to perform the valvular operation than to attempt to remove the prostate by a prostatectomy.

A Modification of Syme's Staff for External Urethrotomy.—Dr. John Van der Poel presented this instrument, which was simply an enlarged tunnel sound with a curve, the sizes running to 24 Fr. The tunnel sound was enlarged to make a better guide in performing external urethrotomy, and acted better than the ordinary small-sized tunnel sound. It was very applicable in cases of extravasation. In doing Harrison's operation, this tunnel sound could be used either before or after the internal urethrotomy; it could be used as a staff upon which to cut. Dr. Van der Poel had found it particularly applicable in the clinical cases and at the dispensary where, with a very tight stricture, it was possible to pass a filiform and the tunnel sound over it. The size of instrument presented was No. 18.

X-Ray Tube for the Intrarectal Treatment of Tuberculosis of the Prostate.—Dr. Sinclair Tousey presented this tube, which was a modification of existing tubes with which were associated the names of Cossar in England and Cauldwell, Morton and

Cleaves in this country. The bulbous portion of the tube consisted of lead, glass opaque to the X-ray. In this there is no platinum disc, but a simple anodal wire at one side out of the way of the cathodal stream which was reflected from the concave aluminum cathode. This stream passed into a cylindrical prolongation of ordinary glass from which it emerged in every direction as diffused X-ray. This prolongation was cooled by an outer tube through which passed a continuous current of water. This portion of the X-ray tube was introduced into the rectum and was excited by a current of about four ampères for about three minutes. The heavily insulated conducting cords which were shown were stated to be a necessary part of the apparatus. The whole was held in hand and with these cords there was no sparking when the wires were touched by the operator or patient, or when the wires became crossed. Equally useful in those cases were high frequency current from the X-ray coil and d'Arsonval transformer. These were applied by means of electrodes consisting of vacuum tubes, some for external use over the hypogastrium and some for intrarectal use. The latter were insulated by a separate outer glass tube where it passed through the anus. The patient held a metallic handle connected directly with one pole of the d'Arsonval transformer and the vacuum electrode was connected with the other pole. When in operation 10,000 waves of violet and ultraviolet light passed down through the vacuum tube each minute and disappeared in the tissue of the patient. There was also a considerable amount of ozone liberated and carried in by the current. Then, too, a current of about 125 milliampères passed through the patient and an easily regulated amount of heat was produced at the point of contact of the glass electrode. The immediate effect of a single treatment was a very active elimination. The effect of a course of treatment has been observed in one case of well-marked tuberculosis of the prostate, which was reported at a recent meeting of the Medical Association of the Greater New York and in which several of our best genito-urinary surgeons, including Dr. L. Bolton Bangs, had regarded the diagnosis as positive. In this case the urine had been full of blood and pus and tubercle bacilli; and the patient had to urinate about 100 times a day. Now the urine contained practically no blood or pus, "only an occasional tubercle bacillus" (Fraser's analysis for two months in succession) and the patient was able to perform social duties requiring him to go five hours without urination and this without discomfort.

A Combined Catheter and Observation Cystoscope, with Demonstration on a Patient.—Dr. Follen Cabot said that the instrument he had just used in catheterizing the ureters of a patient in the adjoining room, was made along the lines of the Brenner and F. Tilden Brown instruments. Here, however, there was no separate chambers for the catheters in either the sheath or attached to the telescope. To support the catheters he had used the telescope and sheath in combination. This had never been attempted, so far as he knew, before. The advantage of this arrangement was, that he was enabled to accurately remove the cystoscope and leave the catheters in the ureters. Also the absence of the separate catheter chambers permitted him to easily clean the instrument. In addition, he had added to the end of the telescopic tube a short individual bridge to support the catheters while being introduced into the ureters. By this arrangement he had devised a curette; also a forceps for grasping any bodies in the bladder, and other instruments which could be made use of without change of tube. A good-sized urethral could be withdrawn from the bladder by this devise. In cases where catheterism was not indicated but an observation only required, the bridge attachment should be placed above the field of vision. It was thus out of the way.

Does Chronic Urethritis Cause Prostatic Hypertrophy?—Dr. E. L. Keyes, Jr., read this paper. He said that the theories of pathologists concerning the etiology of various diseases often aroused but mild interest on the part of the busy practitioner, but when etiological theory impinged upon therapeutic practice the interest of the clinician was stimulated. There were two theories concerning the causes of prostatic hypertrophy; the theory of testicular secretion with its train of castrations and vasectomies, which was a recent memory and the theory of prostatic inflammation which awaited practical confirmation. He gave a brief review of the theory up to the time of Ciechanowsky, who in 1896 published the first of a series of monographs and the conclusions of this conscientious and scientific series of pathological research were: (1) To pulverize through five chapters the remains of the theory of arterial atheroma; (2) to deny the existence of the prostatic adenoma; (3) to attribute the histological changes in both prostate and bladder to chronic inflammation of these organs; (4) to attribute prostatic atrophy and prostatic hypertrophy to similar inflammatory processes differently distributed. He quoted at length some of the experiments of this author from which after an exhaustive study of diseased prostates, Ciechanowsky inferred the very moderate and entirely justifiable conclusion that "The foundation for hypertrophy of the prostate gland and certain forms of prostatic atrophy consisted in chronic inflammatory processes, the etiological relation of which to virulent gonorrhea was not sufficiently proven at present. Yet the great frequency of gonorrhea in general, the great frequency of chronic prostatic inflammation due to it after all acute inflammation had subsided, and more particularly the conspicuous similarity of his observations to the pathological changes found in gonorrheal prostatitis, made it possible that such a relation existed. Whether gonorrhea really was the most freqent and important cause of hypertrophy of the prostate gland, would be the work of the future to decide." The fundamental facts discovered by Ciechanowsky had been verified by Greene and Brooks and by Crandon and were doubtless correct. The conclusion of all these observers was a very direct imputation upon the virtue of the hypertrophied prostate.

Until now the busy practitioner had had no reason to consider gravely the question whether prostatitis was the cause of prostatic hypertrophy, but since Ciechanowsky was so positive and since his demonstrations had been verified by competent, independent observers, it behooved the profession to set prima facie evidence aside and to criticise carefully the seeming freedom from inflammation exhibited by so many cases of hypertrophy of the prostate. Thus clinical evidence might be amassed either for or against the theory.

It happened that he had access to a set of case-books running back to the early sixties, and affording a wealth of clinical material recorded entirely without partisan spirit and detailing urethral histories for many years. From these he had been able to collect a number of histories bearing upon the subject in question; these he submitted with the belief

that they would aid in interpreting pathological facts. His first table of statistics comprised all the cases of which there was the remotest possibility that a previous prostatitis might have been the cause of prostatic hypertrophy. These cases might be divided into four classes: (1) Five cases of chronic urethritis, in which the prostate was not clinically hypertrophied. Three of these showed congestive symptoms of prostatic hypertrophy, but no residual urine, and at most were instances of possible beginning hypertrophy. In two others there was no symptom of hypertrophy, but the prostate was a little large in one and contained a small adenoma in the other. (2) Three cases with partial retention, in which the prostate was certainly not large so far as examination without operation could reveal. These three cases were assuredly instances of contracture of the bladder neck. (3) Three cases of deep stricture, so tight that prostatic symptoms were not revealed, but in which perineal section showed slight enlargement of the prostate. (4) Finally, there remained 15 cases of large prostate, which, with the three mentioned above made 18 cases of known prostatic hypertrophy after more or less prolonged chronic urethral inflammation. These 18 cases were found among 433 case histories of hypertrophied prostate. The number would doubtless have been larger had the cases been more closely questioned as regarded their early history. Their fewness enforces the fact that clinically, prostatic hypertrophy was not often associated with history or evidence of chronic urethritis. Among the 433 cases the degree of enlargement was noted in 192 or 16 per cent., and in the present series the degree of enlargment was noted in 12 cases, thus showing no deviation from the normal standard. The ages at which the symptoms of hypertrophy first manifested themselves were: In the 433 cases below forty-five years of age 3.2 per cent., while in the urethritis series, 5.5 per cent. began before the forty-fifth year. In the larger series 9.5 per cent. began below the fiftieth year, while in the urethritis series 16.6 per cent. began before that itme. In the larger series 14.1 per cent. began after the seventieth year, while in the urethritis series all began before that time. Thus the urethritis series showed prostatic hypertrophy at a slightly earlier age than did the others.

He had collected and tabulated 54 cases of chronic posterior urethritis from various causes, followed to an age varying from fifty to eighty-three years and not associated with prostatic hypertrophy. Among twenty cases of deep stricture, eight of chronic gonorrheal prostatitis and four of stone, the fact that the patients got entirely well under treatment, must be accepted as evidence that they were not suffering from any symptoms of prostatic hypertrophy; otherwise these would have appeared as the symptoms of the urethral or bladder condition were controlled. A third table comprised seven cases of stricture and fifteen of contracture of the neck of the bladder, these cases were all operated upon and the absence of prostatic hypertrophy proven by digital examination. These 54 cases, covering fairly every degree of duration and intensity to be looked for in chronic prostatitis, were sufficiently numerous to prove that chronic prostatitis did not inevitably lead to prostatic hypertrophy. Proceeding on a fair basis of comparisons he found that the percentage of hypertrophied prostates in the urethritis cases were not very different from the percentage in all cases. Thus at the fiftieth year, it stood 25 per cent. as compared to 19 per cent.; while, at the sixtieth year, it stood 33 per cent. as compared to 39 per cent., and, at the sixty-fifth and seventieth years, had fallen relatively lower.

He thought that the most surprising feature of these percentages was the fact that chronic urethritis seemed to have so little effect upon prostatic hypertrophy; if anything, very prolonged and active chronic prostatitis caused atrophy ratner than hypertrophy. In 32 cases the prostatitis lasted more than ten years; of these, 75 per cent. showed hypertrophy, while 12.5 per cent. showed atrophy of the prostate, and not a single one of them had a very large prostate. On the other hand, among the 39 whose prostatitis lasted less than ten years, none showed atrophy, 28.2 per cent. showed enlargement, and two of these were very large. Additional confirmation of this presumption was afforded by the absence of hypertrophy in old cases of chronic retention cystitis due to locomotor-ataxia and other forms of bladder paralysis.

He considered it impractical to draw inferences from the effects of short gonorrheas in early life to the prostatic hypertrophies of later years. It was generally conceded that 75 or 80 per cent. of adult males have had gonorrhea in early life, and that fully 90 per cent. of these have posterior urethritis. Inasmuch as less than 20 per cent. of those who pass their fifty-fifth year have hypertrophy of the prostate, one certainly cannot infer any very direct connection between the two. Additional evidence against such a view was afforded by the fact that prostatic hypertrophy occurred with such uniformity at a definite period of life, which might be called the beginning of the decline. To assume that the prostatitis found by Ciechanowsky and his followers took from twenty to thirty years to produce its effect, was assuming too much for our credence until some direct evidence should be brought forth to support such a theory.

Dr. Keyes said that the following conclusions very fairly expressed his views: (1) Among 433 cases suffering from prostatism, only 18 showed clinical evidence of previous prostatitis. (2) These 18 presented no marked difference in point of the size of the prostate or of the beginning of the disease to differentiate them from the remaining 415. (3) Comparison of these 18 cases with 46 cases of chronic prostatitis without hypertrophy showed that the proportion of such cases suffering from prostatic hypertrophy varied little from the normal. (4) Prostatitis lasting more than ten years probably tended to produce prostatic hypertrophy. (5) Therefore, if it is true that hypertrophy of the prostate was pathologically referable to inflammation, the clinical data suggested that this inflammation was either early gonorrhea of relatively brief duration or some obscure sclerotic process associated with advancing years. (6) The late date at which prostatic hypertrophy began and its infrequency, compared with that of early gonorrhea, made it seem clinically most improbable that early gonorrhea was the cause.

Dr. L. Bolton Bangs said that there seemed to be a great deal of confusion regarding the etiology of prostatic hypertrophy and, after thinking about, reading about and observing these patients for a number of years, if he had any views at all he said he was still open to conviction and willing to be led and taught. He was not satisfied that inflammation was the cause, certainly not the only cause, of enlargement of the prostate. It seemed to him as a result of his own experience, that there was a large class of patients who had led sedentary lives, and that a

sedentary life had much to do with prostatic hypertrophies. He said there was another class of cases in which the hypertrophy began in early life, in some cases before the age of forty, but they were not in sufficient number to warrant any positive statements regarding their etiology. But he had been so struck by this clinical fact that he began to make records of the early sexual life of these individuals and he came to the conclusion that there was a large class of cases in which the prostatic hypertrophy might be attributed to sexual overindulgence of different kinds. There were other cases that seemed to be due to specific inflammation or gonnorrhea, but as other factors were to be considered, he was still somewhat confused regarding the true etiology of prostatic hypertrophy.

Dr. F. Tilden Brown said that practitioners must all admit that they are unable always to interpret the stories by the patients; there was a personal element about the individual which carried conviction or the reverse. He said he had been impressed with the fact that a large number of these patients gave no gonorrheal history. The enlargements of the prostates met with in comparatively early life, during the middle part of sexual activity and under forty years of age, presented to him a different type and did not appear to be a true fibrous enlargement, but practically a turgescence, due to sexual overindulgence. Whether this condition was a factor in subsequent hypertrophy was doubtful.

Dr. Robert H. Greene said, that he had no particular theory bubbling up in his own mind, but that eighteen years ago, being dissatisfied with the vagueness of our knowledge of the pathology of urethral disease, Dr. Ira Van Giesen showed some urethras obtained at autopsies, showing that the formation of true stricture was preceded by a granulomatous condition, and this was preceded in turn by an acute inflammation. These observations have been verified by many and he believed had been universally accepted the world over as being the true condition which existed in the urethra in connection with gonorrhea. Dr. Greene said, he was then interested later on, some six years ago, in finding out how many times the urethra in its deep portion was affected by gonorrhea. There were 216 cases at Bellevue which supplied the required histories. In a large number of cases of gonorrhea the prostatic urethra was invaded. He believed that this fact that had been demonstrated by many men and universally accounted to be so. In making that series of observations at that time he had had the prostate massaged and the secretions examined and through clinical observations he had become firmly convinced for the first time that inflammation played some part in the causation of prostatic hypertrophy, and he read a paper at that time before the Section in Genito-Urinary Surgery of the Academy, expressing those views. He felt convinced that gonorrhea invaded the prostate and set up there inflammatory conditions. Then his friend, Dr. B. Lapowski, told him of Ciechanowsky's work referred to and the reader obtained a copy of it. After reading this work carefully, he went to Dr. Harlow Brooks, the pathologist, and asked him to do some pathological work in connection with his studies and Dr. Brooks consented. In a short time he was able to collect 100 prostates and Dr. Brooks, according to agreement, made the required examinations and their deductions were published after being read before the American Medical Association meeting in St. Paul, Minn., under the title "Fallacy in the Treatment of Urethral Disease." In this article the work of Ciechanowski showing the relationship between inflammation and prostatic hypertrophy was confirmed for the first time. Then more material was gotten together and Dr. Greene and Brooks presented an article entitled "The Nature of Prostatic Hypertrophy." Since that time Craston of Boston had done exhaustive work, and one or two men in Europe, and they all came to the same conclusion. So far as he was concerned, since the articles were published, he did not believe that any pathologist had gone to work without coming to the same conclusions that Brooks, Cienchanowski, himself and other writers had arrived at. It was considered a scientific axiom not to look for anything beyond a simple explanation of a given phenomenon, if that was sufficient, and it apparently was in these cases. As a rule, he said, referring to the remarks made by the reader on the cutting of sections, before the time of the people he had mentioned, he understood that sections had not been made by the investigators through the prostatic urethral part of the enlargement, but through the hypertrophied mass itself; consequently they misled the starting point of the process. When Dr. Brooks made his sections through hypertrophied prostates, he made them through the prostatic urethral portion of the enlargement; they all show scar tissue formation, either a plugging up of the follicles in the floor of the prostatic urethra which later on caused them to swell up and made an enlargement, or scar tissue formation deep down between the follicles and which squeezed them together. To repeat, there was an enlargement caused by a dilatation and distention of the acini, their mouths in the floor of the prostatic urethra being plugged up by scar tissue; in other words, referring to his original question, there was a condition of scar tissue formation in the urethra of the kind that produced a stricture and which had gone into the prostatic urethra in islands and there, the scar tissue not being dense enough to form a stricture, it produced a certain change in the prostate through its action in dipping down between or in plugging up the mouth of the acini, causing either an atrophy or an hypertrophy of the prostate, or a mixed condition of the two. Dr. Keyes, he said, referred to chronic inflammatory processes and Dr. Greene said, he did not exactly understand just what he meant; if Dr. Keyes meant an active inflammation accompanied with the discharge of pus and immediately associated with prostatic hypertrophy that had nothing necessarily to do with the condition; if he meant a chronic granulomatous condition, neither did that have anything to do with it. This condition, Dr. Greene said, of scar tissue formation in the prostatic urethra, which caused later on prostatic hypertrophy or atrophy, was caused by something, probably some cause that had been in action for years. It was natural to suppose it to be most generally due to gonorrhea, as that is, as the reader stated, the common cause of scar tissue in the more anterior portions of the urethra. It might be due to irregular sexual life, possibly to lithiasis. Whatever formed scar tissue in the deep urethra in any given case might be the cause of prostatic hypertrophy.

Dr. Harlow Brooks said that the question might be asked "What is hypertrophy of the prostate?" Years ago it was considered a neoplastic growth. He did not think that any pathologist or clinician, who had carefully studied the condition, would now say that it was neoplastic in nature. Then, what was it? Microscopically it was shown to be due to a hyperplasia of the normal elements of the prostate with certain exceptions, and these exceptions were to be found in the muscular tissue, which did not hypertrophy. What was the cause of the hyperplasia, or hypertrophy? He said that we all know that inflammations chiefly caused the hyperplasia in other organs and he thought this to be the

simplest explanation of what was found in these cases. If sections were studied carefully and the clinical histories gone over with care, he said, one would come to the conclusion that the hypertrophy was inflammatory in nature, but he did not know what caused the inflammation: this was beyond the domain of the pathologist and in that of the clinical investigation, and he did not consider it. He had never stated that the cause was gonorrheal, but simply that it was inflammatory. He said, that he was much disappointed that Dr. Keyes did not give a classification of all the cases of prostatic hypertrophy, classifying those cases in which urethritis was not present but in which hypertrophy was present, as well as those where the urethritis was present but not the hypertrophy. Were the other cases of prostatic hypertrophy presenting inflammatory of syphilitic disease? These were the questions which interested him particularly, and which he thought more important than the relation of any specific type of inflammation to the causation of the condition.

Dr. John Van der Poel said, that it was his belief that in all cases where the posterior urethra was affected the prostate was also. Regarding gonorrhea being a causative factor of prostatic hypertrophy, the figures varied from one-sixth per cent. to 90 per cent. and Frank, of Berlin, gave 33 per cent. His own cases showed a percentage of 39.

Dr. Edward L. Keyes, Jr., closed the discussion by stating that no doubt almost all cases of prostatic hypertrophy had had gonorrhea; but he did not think that prostatic hypertrophy and stricture should be clinically coupled. Strictures came on within a reasonable length of time after an attack of gonorrhea and prostatic hypertrophy an unreasonable length of time after. He said he had collected these cases in order to learn whether prostatic hypertrophy was always caused by gonorrhea, or not; and, as a result of his investigations, he did not believe that it was.

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

Section on State Medicine.

(Continued from Page 618.)

Organization During Peace of Civil, Medical and Ambulance Aid.—Colonel Squire said: That in a war of any magnitude it is necessary to supplement the military organization for the care of the sick and wounded by civilian aid. Such aid is essentially of two kinds: (A) Surgeons, nurses, and orderlies, who are temporarily employed by the military authorities, receiving pay through the War Office. (B) Personnel and stores provided by voluntary subscription. Voluntary aid may be wasteful and embarassing or may be misapplied if no statement of probable requirements and no regulations for their employment have been previously laid down. Organization during peace is essential to ensure the best provision and to avoid unnecessary waste in war. Both classes of aid have occasionally been employed with our troops—for example, in the Crimea, Zululand, Egypt, and the Soudan—but without previous organization and with consequent waste The recent war in South Africa found us for the first time with the germ of an organization, not yet sufficiently developed to meet the requirements of a big campaign, but which nevertheless was of considerable practical value.

Other local issues were discussed:

First Aid in the Tropics.—Colonel T. H. Hendley spoke of the needs of the Indian service. The needs here were great. In six of the largest British Provinces of India—namely, Bengal, the Central and United Provinces, Bombay, Madras, and the Punjab —with an aggregate population of about 209 millions and an area of about 707,000 square miles, in the year 1901 there were 1,991 dispensaries, or one in 355 square miles, or one each for over 100,000 persons, at each of which there were actually treated annually an average of about 10,500 new patients. For some of these provinces the figures for police, mission, and railway institutions are included; and, in others, particularly in Bengal, there are numerous private dispensaries belonging to more or less qualified persons, who practise according to the Western systems of medicine. There are also ex-dressers, compounders, and vaccinators, with many of the followers of the indigenous systems of medicine, of a greater or less degree of ignorance from the surgical point of view; nevertheless, the above statistics, and the deductions from them are sufficiently near the truth for my present purpose. The difficulty may, however, be looked at from another point of view, thus for example if each of the dispensaries were at the centre of an equally accessible district, the most remote of the inhabitants would still be over 10½ miles from a medical man. In the native State of Jeypore the utmost we could do with the available funds was to try to place each individual within 15 miles of such assistance; in Jodhpore the radius was 28 miles; in Jaisulmer there was only one hospital in the state, namely, at the capital, the area being 16,000 square miles.

If we reflect upon figures such as these, I think that we must admit that it is necessary to supplement the regular channels of medical aid, and that this can only be effected by giving such a moderate amount of training as can be acquired with ease and safety by persons of ordinary intelligence, as for example, the headmen of the villages of the vast agricultural population of India. This training must, of course, be of the most practical kind.

Dental Diseases in the Navy.—This was the title of an address by Norman G. Bennett.

Volunteer Brigade Medical Unit.—Brigade Surgeon P. B. Giles read a paper outlining his views as to the personnel of a brigade medical unit. Its duties and functions were about as follows: Duties: First, as the brigade medical unit is formed to place the second and third lines of medical assistance in the field under one command it is obvious that it will have to perform all the duties of a brigade bearer company and field hospital. Secondly, as the increase of establishment provides for one to be detailed to each squad of the various regimental stretcher sections during action they can be employed to teach first aid, bandaging, etc., and so help the regimental medical officer. Also, they should be detailed to supervise the removal of the regimental daily sick to the field hospital. Thirdly, the duties of ward orderlies and other hospital requirements. Fourthly, sanitation being, perhaps, the most important factor for the good health of booths in camp, non-commissioned officers and men should be detailed daily to supervise under the orders of the sanitary medical officer the general sanitary state of the camp, and see that the pioneers do their work efficiently and not in a perfunctory manner. Practically so much value does he place upon this supervision for the general health that he has for years carried

it out with the greatest benefit, and this coming winter course at the Volunteer Ambulance School of Instruction he has devoted a lecture on camp sanitation for the advanced class which consists of men who have obtained A.F.E. 596.

Section on Pathology.

Immunity.—A full discussion on this topic was taken up by Drs. James Ritchie, William Bulloch, George Dreyer, Thorvald Madsen, C. J. Martin, H. Noguchi, M. A. Ruffer, A. E. Wright, and others. The chairman of the section, James Ritchie, opened the discussion, saying that at the present time the theories of Ehrlich, promulgated six years ago, still dominated the entire field. At present three points need to be carefully investigated. These were: (1) The natural immunity observed under certain circumstances to exist toward disease; (2) the artificially acquired immunity which came about in disease contracted under what may be called natural conditions of infection; and (3) the relation of these conditions to recovery in any case of infectious disease. It may be said that at present the direct attack on these problems has been largely overshadowed by the investigation of points which indirectly bear upon them, and especially by the urgent practical necessities which have arisen in consequence of demands made from the therapeutic side of medicine. It thus comes about that our reasonings chiefly are concerned with high degrees of immunity such as do not occur in nature and with artificial diseases whose phenomena elucidate matters under discussion. But how far, for instance, the knowledge accumulated regarding the mode of action of diphtheria antitoxin throws light on the recovery from an untreated attack of the disease, which may of course take place, is still an open question. He first asked what solid basis of fact have been arrived at regarding the process of immunization. In answer, he said, it is known that certain of the effects of some bacteria and most of the effects of other bacteria can be traced to poisons extremely soluble in simple saline solutions; that these poisons are of unknown composition; that they frequently have a selective action on special tissues; that when injected into the body of a susceptible animal they rapidly disappear from the circulating fluids of the body, probably in consequence of being fixed in susceptible cells; that they sometimes, as in the case of tetanus toxin, travel to the sensitive cells by special paths; that by immunization procedures an almost limitless degree of immunity can be developed in a sensitive animal; that such high degrees of immunity are associated with the appearance in the serum of an immune animal of substances capable of neutralizing these toxins; that the action of an antitoxin is specific—that is, it only neutralizes the toxin which stimulated its genesis; that the neutralization of toxin by antitoxin is of the nature of a chemical union; that in its union with antitoxin and also in its union with a susceptible cell, affinities in the toxin cell are saturated, which differ from the affinities to which the essentially toxic action is due. This last deduction is, however, only made from the fact that immunity can be produced by toxins so altered as to have partially or entirely lost their toxic action. To this may be added as an almost certain fact that the union of toxin and antitoxin is dissociable, and that the therapeutic effects of antitoxin, when acting in such a way as to detach toxin from cells to which it is fixed, is dependent on disassociation phenomena. Finally, it may be said, especially from what is known regarding tetanus toxin, that probably the eloboration of toxins may in some way favor the growth of the bacteria producing them, and this may explain why the neutralization of these toxins apparently converts a dangerous organism like the diphtheria bacillus into a relatively harmless saprophyte.

Toxins Specific.—It is to be recognized that the elaboration of soluble toxins is a quality of only certain bacteria, and that in the case of most bacteria, to put the fact in its most intelligible form, not merely the neutralization of poisons produced is necessary if the animal body is to escape destruction but the bacteria themselves must be actually killed. The killing of bacteria is associated with the presence in the serum of an immune animal of two substances, one thermolabile (complement) which naturally occurs in the serum of the animal species involved, and the other, thermostable (immune body), which either is present in normal serum in very small amount, or is altogether absent; that the degree of immunization which can be produced is much smaller than is the case with immunization against toxins; and that this is due to the fact that while an immune body can be formed in large quantity the act of immunization has much less effect on the production of complement. There is the further fact that we are only certain of the specificity of the immune body—that is, we know that immune body will only act deleteriously on the protoplasm which stimulated its genesis. A similar statement regarding complement cannot be made. It is practically certain that the reactions of these two substances on one another, and on the bacteria to be destroyed, are of a chemical nature analogous to the action of toxin on antitoxin, and also that the thermolabile substance has a chemical constitution closely allied to the constitution of toxin. While such results as those of Walker point strongly to the leucocytes being the source of complement, a review of the evidence adduced in favor of a coincident and correlated cytolysis occurring in every case where extracellular destruction of bacteria takes place during life is extremely unsatisfactory.

Toxins and Infections.—The knowledge with regard to the bacteria which by their presence give rise to infections differs in a very important detail from the knowledge of the bacteria acting by means of soluble toxins. In the case of the latter it is certain that it is the presence of the toxin in an animal's body which stimulates the production of antitoxin. In the case of the infective bacteria, on the other hand, it is not known what it is in the bacterial protoplasm which stimulates the production of substances, that is, immune body and complement, capable of killing that protoplasm. This is a point which merits attention here. The infective bacteria manifest their actions in the body by the production of inflammation and of fever. For the concept of fever, he thought it would be well if pathologists substituted the idea of a disturbance of metabolism of which fever may be one of the leading features. Though in the more recent treatments of the subject, such as those of Lazarus-Barlow and Ainley Walker, the metabolic aspects of fever are kept well in view, still in the minds of many the aspect of fever which leads to the explanation of the disturbances of heat regulation has rather a preponderant place attached to it. There is a tendency to look on fever too much in relation to normal heat regulation in the body, and as the other similar pathological processes to leave out of account possible pathological changes in function.

It is practically recognized by all that an increased burning up of the bodily tissues takes place, and it is this increased metabolism with its causes that from the pathological standpoint is really the important question, and it is probably from the consideration of this question in relation to infection that light may come on the true significance of fever as a whole. What the factors in the altered metabolism in fever are cannot be told, but just as in the group of effects which are called inflammation there are those which are the expression of injury done to tissues and those in which we have to recognize the activity of probably unaltered cells, so in fever it will be well to keep a mind open for the possibility that part of the increased metabolism may be the expression of work done by cells actively engaged in operating on the invading bacteria.

The fact that in broad outline the general effects produced in the body by different bacterial infections are similar might be explained in a variety of ways. The important fact is, that the poisonous substances present in infective bacteria do not diffuse out into an ordinary watery medium in which the bacteria may be present. Among the infective bacteria it is generally true that only from old cultures or from younger cultures which have been salted with ammonium sulphate can any poisons be obtained by filtration through porcelain. The most probable source of the poisons is the breaking up of the bacterial protoplasm which apparently frequently, both in cultures and in the living animals, follows on death. This is indicated by the observation of Pfeiffer. The poisons concerned are the so-called intracellular toxins, and by means of them the non-specific effects of the infective bacteria are due. When it is asked what is the relation of these toxins to the rise of immunity against infection, we are in considerable difficulty. And here again the early observations of Pfeiffer working with the cholera vibrio are of great importance, for this observer found that by appropriate dosage an immune animal might exhibit the capacity of killing all the bacteria injected into it and yet succumb to the effects of toxins which the death of the bacteria liberated from the bacterial protoplasm; in fact, might show earlier and greater symptoms of poisoning than the control unimmunized animal. Similar results have been more recently obtained by Kolle working with the plague bacillus, which probably has a somewhat different mode of exhibiting its pathogenic action.

Toxins and Antitoxins.—What is their chemical relationship? This is a pressing question. After reverting to a brief discussion regarding the historical aspects of the subject, he said that notwithstanding the different view points of Ehrlich, Sachs and Morgenroth on the one hand, and those of Madsen and Arrhenius on the other, the principles remain the same and the complexity of the processes have thus far defied analysis. The methods of physical chemistry were coming to the front, however, and he referred to the recent interesting results of Römer and Behring's laboratory, to the effect that when an electric current is passed through tetanus toxin in a U-tube and the moieties of toxin pipetted off from the kathode and anode poles, the examination of the moiety from the former shows that a rise in virulence has taken place. This is a very remarkable result, and if confirmed opens up a most important series of questions.

(To be Continued.)

BOOK REVIEW.

The Ophthalmic Year-Book. A digest of the Literature of Ophthalmology, with Index of Publications for the year 1903. By Edward Jackson, A.M., M.D., Emeritus Professor of Diseases of the Eye in the Philadelphia Polyclinic; President of the American Academy of Ophthalmology and Oto-Laryngology; Ophthalmologist to the Denver County Hospital, etc. The Herrick Book and Stationery Co., Denver.

This bids fair to be a welcome accession to the literature of ophthalmology. In 1872 Nagel began the publication of his well-known Jahresbericht, which has been an indispensable aid to all who would press their acquaintance with the ever-growing mass of printed matter beyond a cursory glance at the journals or books at hand.

When Nagel's Jahresbericht appeared, the original articles relating to the eye had reached annually the number of 600. Dr. Jackson states in his preface that the literature bearing on Ophthalmology is now growing by some 20,000 or 30,000 pages each year. From this comparison it may be seen how much greater the task now is, and how impossible it would be to make a modern Year-Book of Ophthalmology in any sense complete or satisfactory to all classes of readers. As an aid to research, it would be necessary to furnish at least the titles of all articles published, and abstracts of very many that would be of interest to comparatively few readers.

Nagel's Jahresbericht was the work of 20 collaborators, men whose names were among the best known of the time; while the modest volume under consideration is the result of the industry and critical acumen of one man. It is admirable as far as it goes, and fulfils the promises of the announcement—to provide a critical digest of the most important literature of the past year, judging it from the standpoint of the ophthalmic surgeon, and to furnish a list of the most important original communications appearing during the year.

The value of a work like this, the author states, depends, largely, upon its exclusion of all but the most appropriate matter. It is to be hoped that the scope of the work will enlarge from year to year, so that the principle of exclusion will be less prominent, for it is probable that only in this way can a year-book become of lasting value as a book of reference, or anything beyond the too familiar publishers' pot boilers and cumberers of the shelves.

The appearance of the book is excellent, and the few illustrations are satisfactory reproductions of the originals. The index by titles and authors' names is admirable.

BOOKS RECEIVED.

Serums, Vaccines and Toxines. By Dr. Wm. Cecil Bosanquet. 12mo, 344 pages. W. T. Keener & Co., Chicago.

Electrodiagnosis and Electrotherapeutics. By Dr. Toby Cohn. Translated by Dr. F. A. Scratchley. 12mo, 280 pages. Funk & Wagnalls Co., New York and London.

Contributions from the Wm. Pepper Laboratory of Clinical Medicine. Number 4. Alfred Stengel, Director. 8vo, 200 pages. Illustrated. University of Pennsylvania.

Theory and Practice of Infant Feeding, with Notes on Development. By Dr. Henry Dwight Chapin. Second edition. 8vo, 342 pages. Illustrated. Wm. Wood & Co., New York.

ORIGINAL ARTICLES.

THE INCIDENCE OF GASTRIC ULCER IN AMERICA.[1]

BY CAMPBELL P. HOWARD, M.D.,

OF BALTIMORE, MD.;

ASSISTANT RESIDENT PHYSICIAN, JOHNS HOPKINS HOSPITAL, ASSISTANT IN MEDICINE, JOHNS HOPKINS UNIVERSITY.

A MOST casual observer from a general hospital of the north is at once struck by the comparative rarity of gastric ulcer in the medical wards of a more southern institution.

After making the above observation, Dr. Osler suggested that I should look up the statistics. While employed in this task, an invitation came from the Gastro-Enterological Society, and I straightway set about procuring comparative figures. Statistics on any subject are notoriously misleading and can be so juggled as to prove almost any general statement.

In the case of gastric ulcer most writers claim that the only certain way to get the incidence is to search the autopsy records. But do these give one a fair conception? I quite concur with Byron Bramwell,who points out the following fallacies and objections to the post mortem method. (1) All open ulcers are not found; (2) cicatrices of former ulcers are often missed; (3) superficial ulcers probably do not leave a cicatrix when they have healed; (4) some of the scars found may be due to other causes than ulcer, as syphilis, tubercle, etc.

If autopsy records alone are not a fair criterion of the incidence of ulcus ventriculi, let us turn our attention to the clinical data. These prove still more unsatisfactory. In many hospitals almost any case with a history of epigastric pain and vomiting, and the presence of hyperchlorhydria on gastric analysis, is regarded as one of ulcer of the stomach. Every month some cases are admitted to the Johns Hopkins Hospital with the above diagnosis, but a careful investigation of the history and clinical data enable one to unhesitatingly say that the condition is a gastric neurosis, probably a hyperchlorhydria. Some may even give a history suggesting hematemesis. Patients' statements as to hemorrhage are always to be taken *sub judice*. There is nothing more difficult, even for the skilled clinician, to distinguish blood from various other substances in the vomitus. How much more so for the untrained observation of the laity! The physician at times is required to make the most careful microscopical and chemical examinations before his suspicions, aroused by inspection of the vomitus, are confirmed or refuted. That gastric ulcer has sometimes to be diagnosed from the history supplied by the patient, is perfectly true. Yet several factors should be taken into consideration, as the education and intelligence of the patient, his ability to describe things accurately, the extent, frequency and the recentness of the supposed hemorrhage, the character of the medicines used, etc.

At some clinics they go to the other extreme and set a too rigid standard, which may account to some extent for the small number of cases diagnosed in the wards of the Johns Hopkins Hospital.

In spite of all these objections, I feel that by collecting conservative *clinical* diagnoses in addition to the pathological, we can arrive at a much fairer idea of the frequency of ulcer than by pathological data alone.

For this reason I have endeavored to obtain clinical, as well as pathological, data from some of the leading medical centers on this continent. For many years it has been known that the frequency of ulcer in European countries is very variable, and while common as a rule, it is rare in Russia, the Rhine Valley and the Bavarian Tyrol. Various reasons have been assigned for this—climatic, dietary, etc. It is not within the province of this paper to discuss this point.

Many American writers have commented upon the rarity of the disease on this continent. Da Costa in 1881 in his "Text-book of Medical Diagnosis" pointed this out, but gave no figures in support. Keating in the same year found that out of 444,564 deaths in New York City from the year 1868 to 1882, only 410 were assigned to gastric ulcer, or about 0.09 per cent.

Welch coincides with this view, and, in his oft-quoted article in Pepper's System of Medicine, states that he found in 800 autopsies at the Bellevue Hospital, New York, six cases of open ulcer, or 0.75 per cent., whereas the average in Europe is at the most conservative estimate 5 per cent. Thanks to the cooperation of many physicians, I have been able to procure from fifteen hospitals in nine cities situated at the four points of the compass, either clinical or pathological statistics, and from the majority both.

Clinical Statistics.—Let us first consider the frequency of gastric ulcer in America from the clinical standpoint. Out of 16,599 admissions to the medical service of fifteen hospitals situated in eight cities, there have been 930 cases diagnosed as gastric ulcer, or 0.57 per cent.

In Breslau and Zurich between the years 1853-1873 Lebert found 252 cases out of a total number of 41,688 medical admissions, or 0.66 per cent., *i.e.*, 0.99 per cent. higher than the Amercian.

In 42,219 patients admitted to the medical wards of the Charité Hospital, Berlin, between 1888-1898 there were 555 cases of gastric ulcer, or 1.33 per cent., *i.e.*, 0.76 per cent. higher than ours.

[1] Read at the Seventh Annual Meeting of the American Gastro-Enterological Association, Atlantic City, June 6, 1904.

Fenwick, from the London Hospital and from the London and Temperance Hospital, found of 45,712 cases admitted to the medical wards in ten years, there were 383 of ulcer or 0.82 per cent., and in the out-patient department in 5,000 consecutive cases 37 cases, or 0.74 per cent, which gives for hospital and outdoor patients in London 0.78 per cent., *i.e.*, 0.21 per cent. higher than the American.

Byron Bramwell in a clinical lecture in February, 1901, gives the following interesting figures for Edinburgh: Out of 35,692 cases admitted to the medical wards of the Edinburgh Royal Infirmary during eight years there were 803 of gastric ulcer, or 2.2 per cent. And among 7,665 out patients at the above institution, there were 76 or 0.09 per cent. This gives a percentage for Edinburgh in both out and indoor patients of 2.02, or 1.24 per cent. higher than in London and 1.45 per cent. higher than in America.

CLINICAL PERCENTAGE ACCORDING TO HOSPITALS.

Hospital.	Medical Admission.	No. of Ulcer Adm.	Per Cent.
Massachusetts General (Boston)	20,096	351	1.74
Royal Victoria (Montreal)	9,500	92	0.97
Montreal General (Mootreal)	10,966	97	0.88
Presbyterian (New York)	4,537	39	0.86
Boston City (Boston)	13,410	81	0.60
University of Pennsylvania (Philadelphia)	3,979	19	0.48
St. Luke's (New York)	6,153	29	0.47
Roosevelt (New York)	4,765	22	0.46
Johns Hopkins (Baltimore)	16,533	70	0.42
Lake Side (Cleveland)	3,427	13	0 38
New York (New York)	16,235	48	0.29
Cook County (Chicago)1	3,930	6	0.15
Pennsylvania (Philadelphia)	39,730	53	0.13
St. Joseph's (Baltimore)	3,298	4	0.12
Araphoe County (Denver)1	5,040	6	0.12
Total	161,599	930	0.57

If we look at the individual clinical returns from the various American cities, we find that those of the Massachusetts General Hospital (Boston) easily head the list in order of frequency.

PERCENTAGE ACCORDING TO CITIES.

City.	No. Medical Admissions.	No. Gastric Ulcers.	Per Cent.
Boston	33,506	432	1.28
Montreal	20,466	189	0.92
New York	31,690	138	0.44
Cleveland	3 427	13	0.38
Baltimore	19,831	74	0 37
Philadelphia	43,709	72	0.16
Chicago	3,930	6	0 15
Denver	5,040	6	0.12
Total	161,599	930	0 57

Breslau and Zurich	0.66 per cent.
London	0.78 per cent.
Berlin	1.33 per cent.
Edinburgh	2 02 per cent.

Greenough and Joslin,[4] in their excellent paper in 1898, report the figures for ten years, which, with the data for the subsequent four years, supplied me by Dr. Jos. Pratt, of Boston, make a grand total of 20,096 medical admissions, 351 cases of ulcer of the stomach and a percentage of 1.74.

The Boston City Hospital returns I procured for a period of four years from the Annual Reports, and found that of 13,410 medical admissions there were 81 cases, which gives a percentage of only 0.6. This large drop from the above is largely to be accounted for by the fact that many of their admissions are infections.

In spite of this, the percentage for Boston from its two leading hospitals is 1.28, which is 0.62 per cent. higher than the Zurich and Breslau, and even 0.5 per cent. than that of London.

Next to the Massachusetts General Hospital come the returns from the Royal Victoria Hospital (Montreal) with 92 cases out of 9,500 medical admissions, or 0.97 per cent. The General Hospital (Montreal) is a close third with 97 cases in 10,966 medical admissions, or a percentage of 0.88. This gives Montreal a frequency of 0.93 per cent., which is also higher than the German by 0.27 per cent., and the English by 0.15 per cent.*

The returns from three of the New York Hospitals were obtained from their annual reports, and those from the New York Hospital were supplied by Dr. Peabody and his assistant, Dr. Foster. Inspection of these shows the Presbyterian Hospital to be in the lead with 0.86 per cent. (39 ulcers in 4,537 admissions). Those from St. Luke's and Roosevelt hospitals were respectively 0.47 per cent. and 0.46 per cent., while the New York Hospital was still lower with 0.29 per cent., or 48 out of 16,235. Thus for New York the mean is 0.52 per cent., a considerable drop below the figures of Boston, Montreal, London and the Continent.

The Lakeside Hospital (Cleveland) has a percentage of 0.38 or 13 out of 3,427 medical admissions, and is thus fourth on the list of cities.

The figures from Philadelphia are rather puzzling. The University Hospital returns, kindly furnished me by Dr. James Tyson, give 19 cases out of 3,979 admissions, or 0.48 per cent. On the other hand, the Pennsylvania has a very much smaller percentage, viz., 0.13. This discrepancy cannot be accounted for by any apparent reason. Thus for Philadelphia there is a percentage of 0.16, which places it in sixth place.

In Baltimore we meet with similarly anomalous figures. At the Johns Hopkins there have been only 70 cases of gastric ulcer out of 16,553 medical admissions for a period of about fifteen years. This gives a percentage of 0.42, which is far below New York, yet higher than Philadelphia. But in striking contrast are the figures from St. Joseph's Hospital. The medical resident, Dr. Fisher, kindly looked up their records and found only four cases out of 3,298 medical admissions, or only 0.12 per cent. This then gives for Baltimore a percentage of 0.37, very far below

*Since going to print, Dr. Thacher has kindly forwarded me the figures from the Presbyterian Hospital for seven years. Among 10,041 medical admissions there have been 87 cases of gastric ulcer or 0.86 per cent. Among 1,020 autopsies there were 18 cases of gastric ulcer or 1.77 per cent. The latter have come too late to incorporate with the pathological statistics.

New York, and still further below Montreal and Boston.

Figures from Cook County Hospital, Chicago, and the Araphoe County (Denver), are quoted by Greenough and Joslin, and are still lower, being respectively 0.15 per cent. and 0.12 per cent. Exclusive of these two latter figures, it will be noticed that gastric ulcer is very much more prevalent in the North and becomes much less so in the South. On the other hand, judging from the small figures at our disposal, ulcer, clinically, at least, is very uncommon in the Middle West.

PATHOLOGICAL.
(Percentage According to Hospital.)

Hospital.	No. Autopsies.	No. Ulcers.	Per Cent.
Mass. General (Boston)	1 000	29	2.9
Lane Hospital (San Francisco)	551	13	2.35
New York (New York)	561	8	1.43
Boston City (Boston)	2,089	28	1.34
Pennsylvania (Philadelphia)	547	7	1.28
Montreal General (Montreal)	2,286	27	1 18
University (Philadelphia)	279	3	1.07
Lakeside (Cleveland)	413	4	0 92
Johns Hopkins (Baltimore)	2,223	19	0.85
Royal Victoria (Montreal)	872	6	0 69
Total	10,841	144	1.32

Autopsy Statistics.—Of these I have only figures from ten hospitals situated in seven different cities. Among 10,841 autopsies there were 144 open ulcers or their scar, which is an average of 1.32 per cent. Welch collected from the Continent 32,052 autopsies among which he found 1,522 cases or 5 per cent. In London, Fenwick has collected 47,912 autopsy records which yielded 2,019 or 4.2 per cent. Hence it will be seen that in the dead-house, ulcer is about 3½ times more common in England and 6½ times more common in Germany than in America. If we analyze the pathological returns in greater detail, we find that (excluding the figures from St. Joseph's Hospital, Baltimore, where the figure 1 in 66 is too small to be of any value) the Massachusetts General Hospital's returns show the highest percentage, viz., 2.9 per cent., or 29 cases in 1,000 autopsies. Next comes the Lane Hospital, San Francisco, with 13 cases out of 551 autopsies or 2.35 per cent. Third on the list is the New York city, with 8 cases in 561 autopsies, or 1.43 per cent.

AUTOPSY STATISTICS.
(Percentage According to Cities.)

City.	No. Autopsies.	No. Gastric Ulcers.	Per Cent.
San Francisco	551	13	2.35
Boston	3,089	57	1.84
New York	561	8	1.42
Philadelphia	826	10	1.21
Montreal	3,158	33	1.04
Cleveland	433	4	0.92
Baltimore	2,223	19	0 85
Total	10,841	144	1.32

London . . . . . 4.6 per cent.
Europe . . . . . 8.54 per cent.

Arranging the pathological data according to cities, we find San Francisco, which is second as regards clinical returns, is here easily first with 2.35 per cent. Boston next with 1.86 per cent. New York third with 1.42 per cent., as shown by the New York Hospital, the only New York Hospital from which I was able to procure pathological data. This latter is a much higher figure than quoted by Welch from the Bellevue, which was 0.75 per cent., or 6 in 800. Philadelphia is fourth with an average of 1.21 per cent., or 10 cases among 826 autopsies. The average for the two Montreal hospitals is 1.04 per cent., or 33 in 3,158. Cleveland, as represented by Lakeside, shows a considerable drop, having only 0.92 per cent. Lastly comes Baltimore, where, if we exclude the St. Joseph's figures, we have only 19 in 2,223 autopsies, or 0.85 per cent.

Hence it will be seen that the pathological data prove ulcer of the stomach to be very much more common in England and on the Continent than in America; that in the Northern cities, Boston, New York and Montreal, ulcer is more common than in the more Southern cities, Philadelphia and Baltimore. San Francisco, the most southern of the cities of my list being the exception to the rule.

To summarize our conclusions:

1. Both clinically and pathologically ulcer is less frequent in America than in London and on the Continent.

2. That both clinically and pathologically ulcer is more common in the northeastern than in the more southern regions of America, with the exception of San Francisco.

THE CONDITION OF THE BLOOD AND URINE IN GASTRIC ULCER.[1]

BY THOMAS B. FUTCHER, M.B. (TOR.),
OF BALTIMORE, MD.
ASSOCIATE PROFESSOR OF MEDICINE, THE JOHNS HOPKINS UNIVERSITY.

I. THE BLOOD IN GASTRIC ULCER.

The blood in gastric ulcer undergoes very material changes in a certain percentage of cases. These alterations are in large part dependent upon the accompanying hemorrhage. Anemia of more or less marked grade is usually present. As a rule it is of a secondary or chlorotic type.

Before proceeding to the blood changes that are undoubtedly referable to the gastric ulcer, it may not be out of place to say a few words here in regard to the association between the occurrence of gastric ulcer and a pre-existing anemic condition. Samuel and W. S. Fen-

[1] Read before the Seventh Annual Meeting of the American Gastro-enterological Association, at Atlantic City, June 6, 1904.

wick[1] say that there appears to be an intimate connection between anemia and gastric ulcer. In 72 per cent. of their series of gastric ulcer cases in young women there was a definite history of pallor and breathlessness before the first symptoms of the disease manifested themselves. They state that in a large proportion of the others it was highly probable that the patient had suffered from chlorosis shortly before the occurrence of the hematemesis or perforation. They further found that of 100 cases of severe anemia in young women who applied for treatment at the London and Temperance Fever Hospitals four were definitely affected with ulcer of the stomach, and in seven others the symptoms were highly suggestive of the disease. Among a hundred other girls suffering from various complaints the gastric affection was only diagnosed in two instances.

In considering the blood alterations in gastric ulcer, I shall refer briefly to our experience in this connection at the Johns Hopkins Hospital. I am sorry that the blood condition has not been more carefully followed, but blood counts were made in a sufficient number of cases to give us a more or less accurate picture of the blood changes. In the fifteen years since the Johns Hopkins Hospital was first opened there have been 82 cases of gastric ulcer admitted to the institution. To be strictly accurate, there were only 77, the remaining five being cases of duodenal ulcer. In the figures* here given the duodenal have not been kept separate from the gastric ulcer cases, as it has been shown by Cabot and others that there is no apparent difference in the blood findings in the two.

The Red Blood Corpuscles.—The red cells were counted in 44 of our cases. The highest count was 6,780,000; the lowest 1,912,000; and the average of 67 counts in these 44 cases was 4,071,000 per c.mm. The highest count of 6,780,000 was in a patient who had been having considerable vomiting and who had also been on rectal feeding for some time. The polycythemia was probably due to a resulting concentration of the blood. The lowest count was in a patient who on two occasions was thought to be suffering from carcinoma of the stomach, but who was subsequently shown to have gastric ulcer. Where anemia occurred it was usually due to gastric hemorrhage. There were ten cases in which the red cells were below 3,000,000 per c.mm. and two in which they were between 3,000,000 and 3,500,000 per c.mm. The average red count in Cabot's 51 cases was 3,372,000 per c.mm. There were 17 in which the red cells were below 3,000,000 per c.mm.

Cabot says that there is no single disease, so far as he is aware, in which the red cells are apt to be so low, with the exception of pernicious anemia. The anemia he attributes to the hemorrhage, and says that it is uncommon to see marked anemia in gastric ulcer patients who have never had a hemorrhage. Greenough and Joslin[2] report blood counts in 43 of their series of 187 cases, and in only 24, or a little more than 50 per cent., was the red count below 4,000,000 per c.mm. Grawitz suggests that the ulcerative process itself, without any attendant hemorrhage, may cause an actual anemia. Oppenheimer has shown that the pallor in certain cases of gastric ulcer is only apparent, and suggests that it is due to contraction of the superficial capillaries resulting from reflex action on the vasoconstrictor nerves.

The White Blood Corpuscles.—The leucocytes were counted in 45 cases in our series. The highest count was 40,000 per c.mm.; the lowest 1,100 per c.mm.; and the average of 263 counts was 7,500 per c.mm. It was difficult to explain, the high count of 40,000 leucocytes in one case. It was not a leucocytosis of hemorrhage. The average shows that there is no material change in the number of white cells, and these findings are confirmed by Cabot and others. There were no differential counts made in any of our cases. In looking over Cabot's differential counts it is interesting to find that there appears to be a slight relative increase in the small mononuclears in several of the patients, apparently at the expense of the polymorphonuclears.

Practically all observers agree that there is a digestive leucocytosis in gastric ulcer. In cases that have been on exclusive rectal feeding it may reach 12,000 to 15,000 when a rich albuminous meal is given. In our series the digestion leucocytosis was tested in five cases. It was present in all, but the increase in white cells was never marked after the meal, the highest count reached being 10,500 per c.mm. Most authorities agree that the occurrence of a digestion leucocytosis is a point of considerable diagnostic value in cases where the diagnosis is in doubt between gastric ulcer and carcinoma. It does not occur in the latter except in rare instances. Our experience with digestion leucocytosis was too limited to draw conclusions from, but in the cases in which it was tried the increase was too slight to be of much value in a differential diagnosis.

The Hemoglobin.—Of our 82 cases, the hemoglobin was estimated in 44. The highest was 105 per cent.; the lowest 12 per cent; and the average of 62 separate determinations was 58 per cent. In Cabot's series of 51 cases 42, or 80 per cent., had a hemoglobin of less than 50 per cent. The average "color index" in 43 of Greenough and Joslin's cases was 0.67, the highest being 1.41 and the lowest 0.35. Our average color index was 0.72, being very close to that of the latter observers.

The blood picture in our series was that of a secondary or chlorotic anemia, as seen from the following average determinations of the red and white cells and of the hemoglobin: red cells,

* For the figures here given I am indebted to Dr. Campbell Howard, who had already made a complete analysis of our gastric ulcer series, including the blood changes, for a full report to be subsequently published.

4,071,000 per c.mm.; leucocytes, 7,500; hemoglobin 58 per cent.

Owing to the tendency to a supersecretion of a highly acid gastric juice it is generally held that the alkalinity of the blood is reduced.

2. THE URINE IN GASTRIC ULCER.

Certain alterations may occur in the urine. These are not striking nor constant, and may occasionally be accidental and due to some other cause.

Albumin and casts were present together in 14 of our cases; a trace of albumin alone in seven; in 55 the urine was negative so far as albumin and casts were concerned and in five there were no urine notes recorded. No quantitative determinations of the urine were made to ascertain whether the amount of any of the various urinary salts was altered.

Von Noorden finds that albumin is not infrequently present in gastric ulcer, particularly after the severe attacks of gastric pain. Dreschfeld[3] says that albumoses may be present.

Owing to the increased secretion of hydrochloric acid, the urine is often but slightly acid and may even become alkaline. This is especially the case when the stomach is dilated. If the dilatation be considerable, and the fermentation due to micro-organisms increased, the urine may contain an excess of the ethereal sulphates and of indican. Dreschfeld says that the chlorides are often diminished and the phosphates increased. The grade of diminution of the chlorides is dependent largely upon the amount of hyperacidity and the severity of the vomiting.

Acetone and diacetic acid may occur in the urine in gastric ulcer, just as it may in other gastric affections. Lorenz has reported five instances of diaceturia in gastric ulcer, and Dreschfeld three. In some cases the symptoms due to this acid intoxication may be severe. They are usually epigastric pain, persistent vomiting, headache and dizziness. In one of Dreschfeld's cases these symptoms were accompanied by attacks of syncope whenever the patient attempted the slightest exertion. There was a marked acetone odor to the breath and the urine showed both acetone and diacetic acid. Under the administration of citrate of potash by mouth and rectum the symptoms gradually disappeared. The cause of this intoxication has not been definitely explained in gastric ulcer cases. It has been suggested that it may be due to a too strict nitrogenous diet. I have not found any statement as to whether β oxybutyric acid has been found in any of these cases as well. The probabilities are that it is the antecedent of the acetone and diacetic acid, just as it is in the acid intoxication of diabetic coma.

THE PATHOLOGICAL ANATOMY OF GASTRIC ULCER.[1]

BY HARLOW BROOKS, M.D.,
OF NEW YORK.

In taking up the study of the pathological anatomy of this condition it is first necessary for us to define and limit the field of our inquiry. Notwithstanding the question which still invests the etiology, the anatomical picture of "gastric ulcer," in the generally accepted meaning of the term, is distinct and altogether definite.

Nevertheless, to prevent confusion or the possibility of misunderstanding of what I have to say concerning the subject, it is perhaps best to state, in this introduction that I have excluded from this brief study all reference to the rare tuberculous and syphilitic gastric ulcers and to those which we recognize as of traumatic origin, such as are formed by the taking into the stomach of various bodies, as fish bones, pieces of stone or metal or other foreign substances which are mostly found in hysterical or otherwise mentally deranged subjects. Necessarily I have also eliminated those instances in which the ulceration is of escharotic origin, as from the accidental or intentional introduction into the stomach of certain chemical agents, as carbolic acid, various forms of arsenic, alkalies and the like.

Please do not misunderstand me that I mean to infer that true gastric ulcer never follows the traumata resulting from such circumstances, for I do think that in certain rare cases this type of ulceration does follow injury to the gastric mucosa, but only when associated with other conditions, perhaps constantly allied with those productive in the definite anatomical condition which we must as yet perhaps best designate as idiopathic gastric, or peptic ulcer.

For purely anatomical reasons only, I have also excluded in this paper the consideration of duodenal ulcers, though I think we all agree that they are very closely associated with the gastric lesion etiologically and clinically, as well as in their anatomical characteristics.

I find my field somewhat limited in the preparation of this paper in that my subject concerns only the pathological anatomy of gastric ulcer, and since we are to be favored with a paper by Dr. MacCallum dealing only with the etiology, I must refrain from any remarks touching on this, the most interesting and important side of the pathology of gastric ulcer.

As a matter of fact the pathological anatomy of gastric ulcer has been well understood for a very long time and even the older clinical works contain for the most part well-defined presentations of this side of the subject, with accurate descriptions of the lesions. Hence it is, that I must for the greater part but call to your mind facts with which you are all perfectly familiar, and with most of which you have been fully conversant since the days of your undergraduate medical study.

1 Read at the Gastro-enterological Society, Atlantic City, June 6, 1904.

Nevertheless it may be of some interest to you to consider the character of the disease as it is found in various sections of the country, since it is well recognized that even so constant a condition as that which we are discussing varies considerably in different countries, and even in the various parts of the same country. For this reason I shall confine my remarks chiefly to the anatomical aspects of peptic ulcer as we find it in the general hospital service of New York City, and since the greater part of my material is derived from Bellevue Hospital, and particularly from the Fourth Medical Service, with which I have been associated for the past eight years, my facts are chiefly culled from the statistics of this service.

Frequency.—I find in Flint's text-book, which in its day may certainly be considered as authoritative, the following very interesting statements as to the occurrence of gastric ulcer, "Brinton says that gastric ulcer is present in five per cent. of cases of death from all causes. In Prague, where a large number of cases was examined, gastric ulcer was in three to four per cent. In Berlin and Erlangen 4.5 per cent., in Jena 10 per cent., and in Copenhagen 13 per cent." Flint states in happy explanation of these very large percentages, that they were for the most part based on a comparatively small number of observed cases. I have been unable to substantiate these figures from the original articles, except as to Brinton's more moderate statements, but in the light of more modern statistics we cannot but look on them as excessive. It seems to me that statistics in New York may be taken as fairly characteristic of the general occurrence of the disease in the hospital classes, since so large a part of our hospital population, particularly of those presenting themselves at Bellevue, are of foreign extraction or birth.

In looking over my records I have been surprised to find instances of gastric ulcer much less frequent than I had supposed to be the case. Thus in 1,000 consecutive autopsies on adults but nine cases were found. Eight hundred and forty-three of these necropsies, I made personally and I can, therefore, vouch as to the thoroughness of the examination as well as to that of the remaining 157, which were performed by my associates, Drs. Welch and LeWald. These statistics include those in which cicatrization and healing had taken place, as well as those in which the process was still active. Of these nine cases but two had been diagnosticated, a fact which also caused me considerable surprise, for all these patients had been under the observation, in most cases the personal attention of some of the most careful clinicians of New York. One of the undiagnosed cases had been seen by most of the more eminent internists of both this country and Europe, and without a suspicion as to the real nature of the case which finally terminated fatally. In passing, permit me to say that thus far we have found the lesion present in every case coming to autopsy in which the condition had been diagnosticated. These facts led me to search further to try to ascertain if the percentage of diagnostible peptic ulcer was not by chance, smaller than would be the case had a larger number of instances been investigated. Thus taking from the records of the same service before I was connected with the hospital, I find that of 1,366 consecutive histories, gastric ulcer was present in but three instances, a percentage comparing very closely to that of the 1,000 autopsies reviewed in detail by me. A still smaller percentage was found when I consulted the records of the entire medical service of Bellevue for the period of from January 1, 1904, to May 1, 1904, during which time 6,205 new patients were admitted to the medical services of the hospital. In all this number diagnosis of gastric ulcer was made in but three instances. Perhaps you will permit me to state that nevertheless, the visiting staff of Bellevue includes several well-known gastro-enterologists.

Briefly from these observations we are forced to the conclusion that gastric ulcer is a rather infrequent disease, at least as it occurs in a general hospital service, it is quite possible that it is more frequent in well-to-do patients whose habits of life are more liberal. My personal clinical records seem to bear out this statement. It also seems probable that a considerable percentage of these cases, perhaps more than one-half, are not diagnostible clinically, at least by the present methods of the general internist.

Occurrence.—Gastric ulcer is not limited in its occurrence to man only but it is also found in the lower animals, quite frequently, I am informed by Dr. Blair, of the New York Zoological Society, in certain of the domesticated animals, particularly among the *Canidæ*. It is also seen occasionally in wild animals; thus Blair and I found it once, occurring in a Japanese bear in the course of 283 autopsies on wild animals dying in captivity. So far we have not found it present among the ruminants, either those in captivity or such instances as we have had occasion to study in the open.

It is generally conceded that in man the lesion is most frequently found in young women, a statement substantiated by my own statistics and by most of those which I have consulted.

As a rule the ulcers are single, but they are often multiple. Coplin citing a case in which 34 distinct ulcerations were present. Brinton states that two or more are present in one out of every five cases. As a common thing where multiple ulcerations are present the age of the lesions varies and a new ulcer is very apt to occur after the others have completely healed. As an example of this, a recent case of Dr. W. C. Lusk presented an ulceration which was diagnosed and operated upon before perforation was complete. The patient did well for some weeks after the operation but suddenly died with the symptoms of a gastric perforation terminating

with peritonitis, the course of the disease being so rapid that operation was out of the question. It was naturally supposed that the perforation had taken place in the old ulceration, since after a very thorough examination at the time of the operation no other points of ulceration were discovered. At the necropsy we found the original surgical scar which represented the primary ulcer, situated near the pylorus well healed and cicatrized, but a very recent ulceration of the most typical form was found far from the first point of disease and on the anterior surface near the fundus. It is interesting to note in this case that a long-standing salpingitis was present and that other infarctions existed in the organs of their usual distribution.

Location of Ulcer.—Numerous observations have been made as to the points in which gastric ulceration is most likely to be found. Brinton, Ewald, Einhorn and many others have furnished us with statistics on this head, and though minor differences are naturally present, still in a general sort of way they agree on the most important data. From these various figures I have selected the most frequent points of occurrence as follows: First the posterior surface, then the lesser curvature, near the pylorus. They are least common on the anterior wall and at the fundus but may occur at any place, even extending into the duodenum and involving the esophagus. My own personal cases conform more to the data furnished by Coplin and have been mostly found near the pylorus. As will be discussed further on in this paper, the point at which the ulcer is located is of much importance in the prognosis of the case, unfortunately it is usually impossible to determine this clinically, except perhaps in a limited number of instances unless the ulceration be located at or near the pylorus.

Shape.—Gastric ulcers of the type which we are discussing are fairly constant in form. The mucous perforation is almost invariably circular or oval and generally larger than the deepest point of the ulceration so that the general shape of the ulcer is that of a cone or funnel. Not infrequently they are markedly oval in cross section but the longer diameter of the oval bears no definite relation and may be found in any plane. As a general thing the axis of the conical ulceration is not perpendicular to the wall of the stomach but is slightly oblique. It is stated by some pathologists that the shape and location of the ulcer corresponds to the distribution of a definite small blood vessel, and though this has also been my finding in some cases it is still disputed by many observers, and is, after all, more properly considered under the pathogenesis than the pathological anatomy.

One frequently finds a type of ulcer which can hardly be correctly described as conical or funnel shaped, but which should be more accurately defined as "saucer-shaped." In this type the ulcer is usually more shallow and rarely extends deeper than down to the muscle coat. The diameter is proportionately large and the sides instead of being shelving are concave or rounded out. It is quite possible that the more common form may be transformed into the saucer-shape simply by distending the stomach. There is absolutely no ground for believing that the manner of formation differs in either case.

One also occasionally meets with ulcers, even recently formed ones, in which the walls are perpendicular and which look exactly as though they had been punched out by an old-fashioned wad cutter. This form is much more frequent in the chronic ulcers and probably, sometimes at least, is formed from the other more acute types. Where several ulcers have fused, as they are very apt to do, where they are closely approximated, the contour is naturally scalloped, contorted and where the ulcer has spread widely as they occasionally do the borders may even be serpiginous.

The edges of the ulcer in acute cases are generally smooth and sharply cut, giving the characteristic "punched out" appearance mentioned in most text-books. This is the case where the ulcer is seen in its early stages but when it has been of considerable standing the punched-out aspect is obliterated by the presence of irregular areas of cicatrization and masses of granulation tissue. In old ulcerations the typical conical type is also lost and for the same reasons, thus in old cases we not infrequently find the funnel-shape reversed and the ulcer to be undermined, there can be no doubt but that this alteration in shape takes place in ulcers originally of the typical form and that the late stage does not represent the original shape of the primary lesion.

It is important for us to realize that where the ulcerations perforate the walls of the stomach and into other viscera, for example into the tissue of the liver, the conical type of the necrosis is not preserved, but that it is present only in the walls of the stomach. In old cases, as might naturally be expected, induration with more or less elevation of the periphery of the ulcer takes place, again this is a secondary affair and ought not to be considered as associated with the acute primary condition.

Size.—The size of the ulceration varies from very minute, a few millimeters on the mucous surface, to large areas of ulceration perhaps involving, as in a recent case of mine, an area measuring 10 x 15 centimeters, or as "large as the palm of the hand," one author states. It is necessary for us to note, however, that in these excessively large ulcerations secondary infections, as by various gangrene-producing organisms, are usually present or the occlusion or extensive disease of some nutrient vessel of considerable size is demonstrable. Schmaus and Ewing cite a case in which an ulceration extending circularly about the stomach was present. It is probable in such cases that secondary infection from the gastric contents is largely responsible in most instances.

As a rule, the size of the acute ulcerations does not exceed that of a 25-cent piece, according to Einhorn, but in my experience the average ulcer is considerably smaller than the "5-cent piece," which Einhorn mentions as the usual minimum size. I think that all of you who are accustomed to study these ulcerations anatomically will concur with me in the statement that small ulcers are the rule, but the matter of size is of relatively little importance when we realize that the size presented varies much according as to whether the stomach is dilated or contracted at the time of measurement.

Again, I do not think that the size is of such vital import even in prognosis as to healing, and has very little bearing in relation to the serious nature of the case, that is, in all except the very large ulcerations. For instance, Murchison reports a case terminating with fatal hemorrhage, in which the ulceration was but a "pore-like perforation a few lines in diameter" but which nevertheless had opened a vessel of large caliber.

The depth to which the ulceration extends varies, but generally it penetrates at least through the mucosa and submucosa and down to the muscle coats, often, as you well know, it extends through these layers also down to the fibrosa and the peritoneum. Whether it proceeds to actual peritoneal perforation depends, we believe, on the size of the diseased area, and on the rapidity of the necrosis determining the extent to which secondary inflammatory thickening of the subjacent peritoneum can take place, this latter tending, of course, to the limitation of the process at this point. It seems most probable that the depth to which perforation takes place in the subacute or chronic ulcers is more dependent on the character of the secondary inflammation which follows and the nature of the infecting micro-organisms than on the primary lesion. As a rule in my experience the peritoneal infections have been of a more severe character where the perforation is sudden, than where the history extends over weeks or months. Of course there are many factors aside from the virulence of the secondary infecting organisms which enter into the consideration of this statement, but which are largely beyond the legitimate field of this paper.

Ulcer Floor.—The floor of the ulcer, whether it be made up of one of the walls of the stomach, or of some of the adjacent organs, is generally covered by more or less necrotic tissue and blood clot and in the case of old ulcers by granulation tissue, frequently of very low grade.

Microscopical Anatomy.—Microscopically, the chief characteristic of the acute ulcers is the almost complete lack of inflammatory manifestations. The gland tubules are cut sharply off and while the edges of both glands and stroma seem slightly macerated and there is often a slight deposit of fibrin, serum and of a few leucocytes, as a rule very little inflammatory reaction is present, that is in the acute cases and even where the disease is of some days' or weeks' standing we often find the walls of the ulcer devoid of marked inflammatory reaction; perhaps this fact partly accounts for the notoriously slow healing of these ulcerations and in these respects they resemble in a most striking manner the perforating ulcers found in the skin and elsewhere in various trophic disturbances of the nervous system. Often the borders of the ulceration are marked out by a thin zone of necrotic tissue, particularly where the ulcer has been of some days' or weeks' standing.

The necrotic material present in acute cases, in the center of the ulceration shows as a rule in addition to simple necrosis unmistakable evidences of digestion. Bacteria and molds are generally demonstrable.

In the chronic ulcers we find that inflammatory exudation takes place slowly, the result being the production of more or less induration of the periphery of the ulcer. The granulations so formed are generally indolent in character and are very prone to necrose or to eventuate in irregular instead of diffuse cicatrization. Cellular exudation and the production of fibroblasts is generally not very markedly evident, and this finding is borne out clinically by the well-known indolent manner with which these ulcers heal, even under the most favorable conditions of rest and the most approved methods of treatment.

Perforation.—This depends largely, as we have already intimated, on the extent of the ulceration, on the rapidity of the process and on the degree to which the formation of limiting inflammatory membranes takes place as well as on the location of the ulceration, whether it impinges against some other viscus or not. Perforation is thus less apt to take place when the diseased area is opposed against some other viscus, particularly some solid and highly vascular organ such as the liver. It is most apt to follow when only the walls of the stomach intervene between the ulceration and some cavity, thus ulcers situated on the anterior wall of the stomach, particularly those near the fundus, are most liable to early perforation and the causation of terminal peritonitis. In chronic or subacute ulcers perforation not infrequently takes place at a point not corresponding to the site of the ulceration, but pus and gastric contents may infiltrate from this point, dissecting apart the walls of the stomach and finally pointing perhaps at some widely distant place. Such an example recently came under my notice in which the single mucous ulceration was situated near the pylorus in the anterior wall of the stomach. It had penetrated down into the muscle coats of the stomach and between these it has dissected its way downward and backward, finally upward and to the left, eventually perforating the peritoneal coat of the stomach on the posterior surface near the fundus from which point the exudate extended up, finally infecting the left pleural sac, causing empyema.

Where the ulceration be not too rapid and the

opposed viscus becomes glued by peritoneal adhesions to the coat of the stomach, perforation may take place into it, perhaps with very little clinical disturbance, thus frequent instances, some of them unsuspected ante mortem, as seen in which perforations into the colon or small intestine are discovered. Perforation against the surfaces of the liver or pancreas may be accompanied by merely the formation of a thick sheet of fibrous tissue, but often by abscess formation in these organs. It is notable that where other viscera are thus involved, extension of the process, though perhaps very slow, is the rule, the pus gradually dissecting its way, to open in the most unexpected places, perhaps in the perinephritic tissues, in the region of the appendix and so on. In most cases where complete perforation takes place and a fistulous opening against or into some other organ is established, spontaneous healing is not apt to ensue. Perhaps it is not out of place to insert here the statement which has been corroborated by a good many observers, namely that perforation of a true anatomical gastric ulcer, whether into the peritoneum or against some other organ, is more apt to set up a fatal peritonitis or serious suppurative process than is the case where perforation takes place in duodenal ulcer. As has been pointed out, this is probably due to the more nearly sterile character of the material as it is usually found in the duodenum and probably to the greater facility with which limiting adhesions are formed in this region. Pyloric ulcers are for these same reasons also somewhat less apt to cause serious complications.

The possibility of ulceration into the walls of a vessel of considerable size must be considered in even very small ulcers in which case fatal hemorrhage may occur too rapidly for surgical intervention in even the most favorably situated hospital cases. Coplin states that 3.2 per cent. of the cases perforate into the peritoneal cavity, this is a somewhat larger percentage than most observers have noted.

It is unnecessary for us to consider here all the lesions which may arise from perforation since they depend almost entirely on the portion in which the perforation takes place, the direction in which the material infiltrates and on the nature of the secondary processes which arise as a consequence of the infection, with these you are all perfectly familiar, and I have perhaps sufficiently indicated the general conditions which determine the complications from the anatomical standpoint.

Healing.—There can be no doubt but that a large number of gastric ulcers of small extent occur and heal without producing symptoms sufficiently marked as to cause the patient to consult a physician. Thus where the ulceration does not extend deeper than into the submucosa and is so minute as to be little more than a simple anatomical erosion of the mucous membrane, granulations springing up from the highly vascular connective tissue of the gastric submucosa fill in the space, and subsequently contraction and cicatrization leaves the area marked by but a small point of retracted and adherent mucosa very frequently of a stellate form. In my opinion, it is very doubtful if glandular hyperplasia plays any rôle in such a healing process, I am inclined to think that many of the small white points and nodules of thickening which we commonly find in the mucous membrane of the stomach at post-mortem examination and which microscopically are made up of firm adult connective tissue, generally surrounded by a certain amount of cellular exudate, are really formed in this manner and that they represent minute healed gastric ulcers. I do not think, however, that we are justified, as some observers assert, in concluding that most or all scars of the mucous membrane represent old gastric ulcers, many of them are probably simple cicatrices formed after traumatic injuries of the gastric mucosa, perhaps even after simple mucous desquamation. From the study of the healing process in gastric ulcer I am convinced that where healing takes place, it is usually from granulations which spring from the base of the ulceration more than from the sides, though it is quite possible that those originating from the lateral aspects of the deeper perforations also enter into the reparative process, but from my observations to a much lesser degree. Perhaps this accounts for the marked tendency to infiltration and dissection along the sides of old gastric ulcers, while the floor is often rendered firm and practically impermeable by the formation of thick sheets of hyperplastic fibrous tissue.

From my cases I am inclined to think that in the larger ulcerations at least little is to be expected in the way of glandular hyperplasia and epithelial reproduction of the diseased mucosa over the ulcerated area, in some cases this does take place to a limited degree but the tubules so formed as they are generally found about the periphery of the old ulcerated area are atypical, their relation to the stroma is not normal and probably the deficient vascular supply prevents the possibility of complete normal restitution of so complex a structure. Thus it is that we generally find healed ulcerations marked by a firm base of connective tissue, sometimes partly covered in by an atypical epithelial layer, but rarely showing normal glandular structure.

In a good many cases, serious distortion of the stomach is produced by the contraction occurring in cicatrization of gastric ulcers, thus pyloric stenosis is occasionally seen, or even, if the ulcer be situated in a broader portion of the cavity, stellate scars of such extent as to seriously compromise the stomach may be found. Adhesions to the surrounding viscera may also be so extensive as to give rise to a good deal of disturbance.

Where an ulcer has been of long standing one commonly finds the mucous membrane surrounding the ulcer completely displaced for a consider-

able distance and represented by a layer of hyperplastic connective tissue infiltrated by leucocytes, plasma cells, lymphocytes and permeated by newly formed blood vessels and fibroblasts, glandular structures may be entirely wanting and yet gross examination may show but very little apparent alteration.

I do not wish to close this paper concerning the anatomical characteristics of gastric ulcer without placing myself among those who believe that primary gastric carcinoma frequently arises in the healing lesions. Two of my cases of gastric cancer show this distinctly, both in their clinical history and from the subsequent anatomical findings, and while many investigators have asserted this relationship others have disputed it. It seems to me, considering gastric cancer in its relationship to the formation of carcinoma elsewhere, that no more favorable circumstances for the excitement of an abnormal epithelial proliferation could exist than is found in the borders of an old gastric ulcer where gastric contents and secretion add their irritation to that of chronic inflammation and cicatricial formation.

COMPLICATIONS AND SEQUELÆ OF GASTRIC ULCER.[1]

BY MORRIS MANGES, M.D.,
OF NEW YORK;
PHYSICIAN TO MOUNT SINAI HOSPITAL; PROFESSOR OF CLINICAL MEDICINE, NEW YORK POLYCLINIC MEDICAL SCHOOL.

ACCORDING to their origin, the complications and sequelæ of gastric ulcer may be classified into two great groups:

(I) INTRAGASTRIC, (II) EXTRAGASTRIC.

I. Among the intragastric are:
1. Hemorrhage.
2. Profound anemia.
3. Interference with motility of the stomach (if the lesion extends deeply into the muscularis, being thus independent of such interference with motility which might arise from stenoses or perigastric adhesions).
4. Stenosis, of which we have: (*a*) Cardia, (*b*) Pylorus, (*c*) Body of stomach (hour-glass stomach).
5. Gastrosuccorrhea with its various complications, such as tetany, etc.
6. Carcinoma.

II. The extragastric include:
1. Perforation (*a*) free, (*b*) with adhesions, (*c*) with adhesions and suppuration (subphrenic and other abscesses, fistulæ of various kinds), (*d*) general emphysema.
2. Perigastritis (*a*) localized thickening of the serosa, (*b*) adhesions to various organs, (*c*) displacements of the stomach, (*d*) distortion of the stomach.

[1] Read at the Seventh Annual Meeting of the American Gastro-enterological Association, held at Atlantic City, New Jersey, June 6-7, 1904.

To enter into any extended discussion of these various complications and sequelæ is unfortunately impossible, since the time alloted is all too brief, and, furthermore, some of these topics will be considered by other speakers in this symposium. I believe, therefore, that I will best subserve the object of this symposium if I present some illustrative cases which have occurred at the Mount Sinai Hospital during the past few years.

For this purpose, with the aid of Dr. Edward A. Aaronson, I have studied the records of 216 cases of ulcer and cancer of the stomach which have been admitted to the medical and surgical services of Mount Sinai Hospital from 1898 to the present time.

Ulcer of the stomach	52
Carcinoma of the stomach	142
Benign pyloric stenosis	15
Perigastritis	7

In this series of 52 cases of gastric ulcer there were the following complications:

Hematemesis	10
Perforation	4
Perigastritis	2
Intestinal obstruction	1
Thrombosis of splenic vein, subphrenic abscess, gangrene of spleen, abscess of liver, and necrosis of lung	1

Sequelæ of gastric ulcer:

Carcinoma	4
Pyloric stenosis	6
Recurrence	2

It will thus be seen that this series only includes certain of the complications and sequelæ which may arise in this condition, but for reasons above stated I shall confine myself to these. Furthermore, in many cases the fragmentary character of the histories and the poverty of details as regards the chemism of the stomach contents, so desirable in the consideration of all cases of stomach disease, are due to the fact that many of these cases, when admitted to the hospital, were desperately ill. Nor will all the cases be considered, but only such as illustrate some special feature of interest.

I. HEMORRHAGE.

Of the ten cases of hemorrhage I shall refer to but one, since the loss of blood was so great and so uncontrollable by medical treatment that surgical interference was necessary.

Case I. Gastric Ulcer; Hematemesis; Profound Anemia; Gastrotomy; Cauterization of Gastric Ulcer, and Gastro-enterostomy; Death.[1]—Fannie S., eighteen years of age, was admitted July 25, 1901, to the medical division of the hospital under the care of Dr. H. Berg. Present illness began two weeks prior to admission with severe pains in the epigastrium, recurring every two or three hours, each paroxysm lasting about half an hour. Up to three days before admission there was no vomiting. Then she vomited a large quantity of bright red blood (according to her statement, about one quart). The bloody vomiting recurred the following day; stools tarry.

[1] Mt. Sinai Hospital Reports, Vol. III, p. 98.

On admission a blood count showed 3,500,000 red cells, 12,000 white cells and 50 per cent. hemoglobin. During her stay on the medical side of the hospital (six days) the patient at different periods vomited large quantities of blood. Her pulse became steadily more rapid and feeble and general condition progressively worse. The medical treatment being unsuccessful, operative interference was decided upon, and the patient was referred to Dr. A. Berg for operation.

The presence of the repeated hematemesis naturally rendered it impossible to present any report on the chemism of the stomach. When transferred the patient was exsanguinated; the pulse 156, soft and thready; hemoglobin 30 per cent. General anesthesia being inadmissible, the operation was done under eucaine anesthesia, and was performed at the express request of the attending physician.

Operation.—Incision, six inches long, downward from the ensiform cartilage. The peritoneal cavity being opened, the stomach was at once exposed. On handling the stomach patient complained of nausea. She then vomited several ounces of black blood and a large clot. Inspection of the anterior wall of the stomach and palpation showed no indications of an ulcer. Palpation of the posterior wall revealed an area of induration near the pylorus and close to the lesser curvature, which was about the size of a ten-cent piece. The stomach was delivered into the wound, and the peritoneum was walled off by iodoform-gauze packings. An incision, about four inches long, was made through the anterior wall of the stomach parallel to its long axis, one end being at the pylorus. Four silk fillets were passed, at each angle, through either margin of the incision, and its edges were separated by traction. A quantity of dark-colored blood was wiped out of the stomach. Digital exploration of the suspected area revealed an ulcer. Hemorrhage had ceased. By means of four broad retractors every part of the mucous surface of the stomach was successively exposed to view, demonstrating that no other ulcer was present. The floor and margins of the ulcer were seared with the actual cautery. A large vessel could be felt pulsating immediately underneath the floor of the ulcer. This circumstance forbade a deep cauterization.

The gastric incision was closed, in its pyloric portion, with a double row of continuous Lembert sutures. The other angle of the wound was utilized for the establishment of an anastomosis with a coil of the jejunum (Murphy button). Peritoneal toilet; closure of the abdomen.

Duration of the operation, one hour. During the entire operation the patient complained of air-hunger; the pulse flagged so rapidly that two saline infusions, of sixty ounces each, were administered.

The patient never rallied and died fourteen hours after the operation.

A fundamental rule of medicine is the checking of dangerous hemorrhage. There is no reason why a dangerous hemorrhage issuing from the stomach should form an exception to this rule. It seems that in this case more prompt interference might have checked the hemorrhage and eliminated the ulcer.

This is the only case in which hemorrhage required surgical interference, and was the only one of the ten which was fatal. This result is rare in so young a patient, since, as shown by Moulin,[1] death from hemorrhage in gastric ulcer in women under thirty years of age, occurred only once in 153 cases. In women over thirty years of age it occurred in six per cent. of the cases, while in men over thirty years old it was still more frequent, *i.e.*, in 12½ per cent. of the cases.

The indications for operative control of hemorrhage in gastric ulcer is by no means a subject on which all writers are agreed. It is, however, generally accepted that in a single large hemorrhage it should only be resorted to after all medical methods have failed to control it. That even as a last resort, much can be accomplished, is shown by the numerous successful cases reported in the English medical journals during the past few years. Leube would find an even greater indication in repeated small hemorrhages,—a class of cases in which experience has shown cancer, rather than ulcer, is more apt to be found.

2. PERFORATION.

Perforation presents a group of symptoms dependent entirely upon the mode of onset. This may either be acute and is then associated with the discharge of the stomach contents into the free peritoneal cavity, or it may be slower and preceded by the adhesion of portions of the gastric wall to one or more of the surrounding viscera. How varied the latter course may be is well known, and the results of this slow perforation constitute some of the most striking findings at the operation table and at autopsy. Thus, the perforation may be into any of the adjacent organs—liver, pancreas, spleen, transverse colon (fecal vomiting), portal vein (pylephlebitis); or, the course may be upward through the diaphragm and the perforation even into the pericardium or into the heart. The pleura and lung may be invaded and even costal cartilage may be attacked. Finally, fistulæ may reach the surface, thus giving rise to gastro-cutaneous fistulæ. In some of the various perforations into the neighboring organs, which are associated with suppuration, we have the different types of perigastric subphrenic abscess. Another complication of perforation, which is extremely rare, is general subcutaneous emphysema.

Among the cases of perforation the following may be referred to:

Case II. Ulcus Ventriculi; Perforation; General Peritonitis; Gastrorrhaphy; Death.—J. M., twenty-two years old, Russian, a waiter, was admitted February 9, 1903. He was absolutely

1 Lancet, 1902, Vol. II, p. 17.

well up to the time of his present illness, which was of sixteen hours' duration. It began suddenly with severe cramp-like pains around the umbilicus, soon followed by pain in the right iliac fossa. He vomited five times last night and twice this morning, the last time eight hours ago. The vomitus was brownish in color but contained no blood. At present he has considereable nausea. Bowels moved last two days ago.

Physical examination: General condition very poor, cyanotic, restless. Temperature 101° F., pulse 132. The abdomen was moderately distended and very rigid; some tenderness all over the abdomen which is very marked in the right iliac fossa; movable dulness in the flanks on change of position of the patient. No mass palpable.

Immediate operation by Dr. Moschcowitz. The appendix was first sought for and found normal. On opening the peritoneum there was a gush of two quarts of odorless purulent fluid. The intestines were closely examined for a perforation, but with a negative result. The abdominal incision was carried upward and on careful search a perforation on the anterior wall of the stomach, about the size of a pea, was found one inch from the pyloric groove. Gastrorrhaphy and peritoneal drainage concluded the operation. Culture from the peritoneal exudate showed *Staphylococcus aureus*.

The condition of the patient became worse and death occurred on the day following operation. No autopsy.

The latency of the pain is the most striking feature of the history, although possibly, had the patient's general condition permitted it, some symptom pointing to the gastric ulcer would have been elicited. To have made an accurate diagnosis of perforation of an ulcer was absolutely impossible before operation, but that there had been a perforation of some viscus with free fluid in the peritoneal cavity was very evident.

Case III. Ulcer of the Stomach; Perforation; General Peritonitis; Death.[1]—A. G., female, thirty-four years of age, was admitted to the hospital moribund. She had never been ill until four days before admission. Then she complained of adbominal cramps, specially marked in the right iliac region, nausea, vomiting and constipation. She was sent to the hospital for intestinal obstruction but no operation was deemed advisable, and she died soon after admission.

The autopsy revealed a clean-cut perforation of the stomach, about half a centimeter in diameter, located in the lesser curvature near the pylorus. Its edges were thickened and infiltrated. There were free gas and a large amount of brownish fluid in the peritoneal cavity. The spleen lay in a sac, made by adhesions, filled with fluid. Microscopical examination of the edge of the perforation showed that the infiltration was entirely inflammatory. The usual lesions found in cases of status lymphaticus were also present.

[1] Mt. Sinai Hospital Reports, Vol. I, p. 178.

The result in the next case of perforation was better, since the operation was successful in spite of the presence of a diffuse peritonitis.

Case IV. Perforation of Gastric Ulcer; Diffuse Peritonitis; Operation; Recovery.—R. L., eighteen years of age, Russian, tailoress, was admitted October 24, 1901. The history given is that for five years she has had frequent attacks of pain over the right side of the abdomen and in the epigastrium, radiating to the right shoulder. Has heartburn before these attacks, which come on after eating food. Vomiting immediately relieves the pain. No hematemesis; no melena. Present illness began three days ago, after six months' respite from the above attacks. She went to bed yesterday when she suddenly grew weak and faint, this being the first time that she had to go to bed. Pain for the first time began in the left shoulder and then in the abdomen where she had severe cramps. No vomiting; bowels constipated.

Physical examination showed a rigid abdomen, tympanitic, and marked tenderness over the epigastrium, left hypochondrium and right iliac fossa. Rectal examination was negative. At time of admission temperature was 103.4° F., pulse 120.

Operation was immediately performed by Dr. A. A. Berg. On opening the abdomen some clear fluid escaped. Palpation of the appendicular region by the finger gave negative results. In the epigastrium a number of adhesions were felt between the stomach, gall-bladder and liver. After the upper peritoneum was incised there followed a gush of gas and thin greenish-white fluid. On lifting up the left lobe of the liver a greenish fluid and gas bubbles were seen to exude from the stomach, and a perforation was found on the anterior wall in the cardiac portion near the greater curvature. The perforation was the size of a pea and about it the stomach was infiltrated. After repair of the perforation the wound was closed and a rapid improvement in the patient's condition followed.

October 29.—No vomiting for two days; condition very good; fluids by mouth.

November 4.—Temperature rose to 103.8° F. Complains of pain in the left shoulder. Some dulness over the right lung posteriorly. There was also an area of dulness posteriorly in the left hypochondrium.

November 5.—Aspiration in the left subphrenic space negative.

December 23.—After a fairly smooth course the patient was discharged cured, all symptoms having disappeared.

None of the cases of perforation of gastric ulcer occurred in patients who were under treatment for gastric ulcer in the hospital, but were admitted for perforative peritonitis, or, as in Case III, for intestinal obstruction. The histories obtained from these patients did not permit the making of a correct diagnosis.

The histories of Cases II and IV are quite typi-

cal of what occurs when the perforating ulcers are situated on the anterior wall, in which, as is well known, adhesions seldom occur. That an ulcer near the lesser curvature should act in this way is more exceptional, since the antecedent adhesions which generally form with these ulcers usually determine slow perforation with the formation of a subphrenic abscess. Case IV has added interest, since the adhesions which were found between the stomach, liver and gall-bladder, were associated with another ulcer, probably of longer standing, situated near the pylorus or on the lesser curvature. The perforating ulcer, which caused the urgent symptoms, was found on the anterior surface and had no protective adhesions.

One point may deserve reference, namely, the latency of the symptoms in many cases of perforation, even where extensive adhesions have formed about the stomach. Of the many instances of this kind which might be cited, none is more striking than the case reported by Ashhurst.[1] This woman, fifty-seven years old, had no complaints beyond some discomfort from what she called "wind on her stomach." Shortly before she was found dead in bed at night she had had some sharp pain, of which she complained but little. Two quarts of foul pus were discovered in her peritoneal cavity, and two perforations in the stomach, one on the posterior surface, the other high up near the lesser curvature and opening into a ruptured abscess cavity under the left lobe of the liver.

The possibilities of surgical treatment of perforation, even under the most adverse circumstances, are too well known to require any special discussion.

The next case presents a number of unique features and is as follows:

Case V. Perforated Gastric Ulcer; Subphrenic Abscess; Thrombosis of Upper Branch of Splenic Vein; Infarction and Gangrene of Spleen; Necrosis of Lung; Abscess of Liver; Sepsis; Death.[2]—S. F., female, thirty-three years old, was admitted June 23, 1898, to the service of Dr. Gerster. Had been under treatment for gastric ulcer. Seven weeks before admission she had sudden pain in the umbilical region and since then has had continuous fever, at first with, later without profuse sweats; no chills. Vomiting of intensely fetid fluid.

On the left side dulness extending from the lower border of the ribs to the sixth space posteriorly, apparently connected with a tumor mass in the left hypochondrium. Occasionally, after vomiting of fetid fluid, the dulness was replaced by tympanitic resonance with succussion.

June 24.—Aspiration in eighth left intercostal space, axillary line, withdrawing brown, decomposing pus, containing particles of food. Longitudinal incision along needle; seventh and eighth ribs resected; pleural cavity walled off by gauze packings; diaphragm incised, and a large cavity opened into, situated in retrogastric space, its upper anterior wall formed by a gangrenous part of spleen, its anterior wall formed by a posterior surface of stomach, and communicating by an opening through the diaphragm with an abscess cavity in the lung. The cavity was filled with fluid with peculiar methyl alcohol odor. The gangrenous portion of spleen was easily removed. At bottom of cavity was seen a large gastric fistula, which could not be repaired on account of the necrotic condition of the neighboring parts. Cavity evacuated and drained; fistula plugged.

Cultures from the gangrenous spleen showed pure cultures of the *Bacillus proteus vulgaris.*

June 25.—Profuse discharge of material from stomach and necrotic tissues of the wall of the cavity. Posture did not affect gastric discharge.

July 1.—Death from inanition and sepsis.

The post-mortem examination which was made by Dr. Libman, was restricted to the parts in the neigborhood of the wound revealed a very unique state of affairs. In the fundus of the stomach there was a fairly circular opening about six centimeters in diameter. The mucous membrane was everted and had firmly grown to the serous coat of the stomach. From the edge of the perforation ran a vein filled by a partially organized thrombus, which anastomosed with the splenic vein. The thrombus was continued into the upper branch of the splenic vein. The spleen was necrotic at its upper end and was ragged. A large piece of its upper pole was missing. About the middle of the spleen was a raised margin, above which the spleen was swollen and congested. This area, together with the piece missing, was taken to represent the area normally drained by the upper branch of the splenic vein. The diaphragm was perforated at the base of the left lung and there was a defect in the lung. The edges of the perforation of the diaphragm were adherent to the lung. The lung itself was normal, excepting the lower half of the lower lobe, which was in a state of chronic interstitial inflammation. There had evidently been gangrene of part of the lower lobe, and the gangrenous area had completely separated. In the left lobe of the liver, posteriorly, was a large cavity containing pus and having a ragged, necrotic wall infiltrated with pus. The vessels supplying the part could not be examined.

In the differential diagnosis of perforation I wish to report the following case of ulcer and hematesis with pseudoperforation, that is, the occurrence of symptoms which indicated perforation and yet operation showed neither perforation nor peritonitis, but only an ulcer on the lesser curvature.

Case VI. Gastric Ulcer; Hematemesis; Pseudoperforation; Laparotomy; Ulcer found on the Lesser Curvature; Gastro-enterostomy; Recovery.—S. V., female, twenty-seven years of age, native of the Danish West Indies, domestic, was admitted December 16, 1903, with the history that

[1] Amer. Jour. of the Med. Sciences, Oct., 1902, p. 629.
[2] Mt. Sinai Hospital Reports, Vol. I, p. 178.

she had had no gastric symptoms previous to two years ago, but for several years has had headache, dyspnea on exertion and cardiac palpitation. For the past two years she has been subject to attacks lasting a month or more, the first symptom of which was a sharp pain under the lower sternum and in the pit of the stomach. The pain radiated around the lower left chest to the back, was sharp in character, worse on motion of the body, coughing and on deep inspiration. Vomiting occurs at least once a day during these attacks and there has been hematemesis. The attacks are followed by intervals of relief lasting several months.

She has now had pain and vomiting for two weeks, and during this time has vomited blood three times, always about a mouthful. The time of vomiting bears no relation to eating or coughing. There is absolute anorexia and nausea during an attack. No pain in the right hypochondrium. Bowels regular; feces normal. Has been in bed since last hematemesis, five days ago.

Physical examination showed general condition good; fairly well nourished. Tongue moist and coated. No icterus. Small submaxillary glands; other glands negative. Percussion over the dorsal and lumbar spines causes pain. Lungs, heart, liver and spleen negative. In abdomen slight prominence in the upper part of the left rectus where there is some increased rigidity. Tenderness in the epigastrium extending down to the level of the umbilicus, more marked over the upper rectus and left hypochondrium, otherwise negative. Hemoglobin 78 per cent.; red cells 4,120,000; white cells 10,200.

December 19.—Vomited bile-stained fluid for the first time.

December 21.—Nutritive enemata since admission with no relief from gastric pain. Abdomen still tender and constant nausea with occasional bile-stained vomiting. No blood in the stool (guaiac test).

December 23.—After six days of rectal feeding acetone and diacetic acid appeared in the urine. Epigastric tenderness diminished. Pain is paroxysmal.

December 26.—No vomiting for the past two days, but is still tender.

December 28.—Barley water by mouth. Hemoglobin 78 per cent.; red cells 4,080,000.

December 29.—Marked epigastric tenderness; no nausea or vomiting. Increased pain.

January 2.—Vomited once last night and again this morning. This A.M. vomitus contained old blood. Rectal feeding has been continued for past seventeen days with only water by mouth. Very little epigastric tenderness.

January 7.—No tenderness or gastric symptoms.

January 13.—Vomited four times in past twenty-four hours; last vomitus contained ʒii of dark clotted blood. No rigidity of recti.

January 20.—No vomiting in five days. Slight tenderness in epigastrium.

January 23.—Vomitus to-day showed no free hydrochloric acid; no lactic acid.

January 29.—No vomiting in six days. Still has tenderness in epigastrium and hyperesthesia of skin on left side of the back. Vomited this afternoon. This evening has intense pain in the epigastrium. Temperature 102.2° F., pulse 112. No signs of shock. Tenderness most marked in the epigastrium and diminishing to a finger above the umbilicus. No increase of rigidity. Respirations are 30 and abdominal. Liver percusses to the free border; flanks tympanitic.

January 30.—3 A.M. Pulse 140; temperature 103° F. Increased rigidity in the epigastrium and Dr. A. A. Berg advised exploratory laparotomy. 7 A.M. Operation. An ulcer was found on the lesser curvature near the pylorus. There was neither a perforation nor any peritonitis. A gastro-enterostomy was performed.

March 5.—The subsequent course was uneventful. All the symptoms disappeared and she was discharged cured.

The urine was always negative, except for a trace of albumin and an occasional hyaline cast.

The reason for the absence of report of stomach analysis in this case is that the acuteness of the symptoms of gastric ulcer did not warrant the use of the tube.

The explanation of the acute symptoms is by no means easy, especially in view of the absence of perforation or peritonitis as revealed at the operation. The diagnosis of perforation seemed warranted by her condition before the operation. The exploratory operation seemed justified by the increasing severity of the symptoms and the happy outcome of the gastro-enterostomy demonstrated its usefulness.

Another case which shows the difficulty of the interpretation of attacks of pain occurring during the course of gastric ulcer, was the following in which operation revealed an intestinal obstruction, although the symptoms indicated perforation.

Case VII. Gastric Ulcer; Sudden Severe Pain; Symptoms of Perforation; Intestinal Obstruction; Death.—F. S., male, thirty-two years of age, brassworker, admitted December 7, 1903, transferred to surgical division December 9.

Previous history: For the past seven years there has been gastro-intestinal disturbance. Six years ago was in a hospital abroad suffering from abdominal pain and distention.

Present history: Duration indefinite. There has been a gradual increase in the severity of the gastric symptoms, *i.e.*, he has had pain in the whole abdomen, worse after eating and at night (Reichmann's disease). Occasional vomiting about an hour after eating; no hematemesis. Yesterday the vomitus contained black particles. Considerable loss of flesh and strength. Bowels very constipated. No tenderness. Urination normal. He felt very weak during the past month and has been in bed most of the time. Pressure exerted by lying on his abdomen relieves the pain.

Distention comes on about an hour after ingestion of food.

Physical examination: General condition good. Aphthous stomatitis present. No glandular enlargement. Lungs, heart, liver and spleen negative. Examination of stomach area shows a swelling in the upper abdomen extending to just below the umbilicus, showing slight peristaltic movement. Succession to level of umbilicus. Urine negative. Stomach contents were not obtainable as the patient objected to the use of the tube.

December 9.—Last night and this morning the patient had a severe attack of abdominal cramp-like pain referred to the umbilical region. No increase of the pulse rate nor rise of temperature. Abdomen held rigid; no tenderness. In the morning the patient was relieved by morphine. In the afternoon the pain continued; abdomen distended and general tympany; nothing palpable. Bowels did not move after high enema. Patient rapidly grew weaker, pulse more rapid, and perforation being suspected he was seen by Dr. Berg, who decided to operate at once.

Operation at 9 P.M., and by this time the condition was so poor that only local anesthesia could be employed. Pulse had risen to 170. The stomach was first washed out and about two quarts of black fluid evacuated, after which the abdomen became almost flat. Posterior gastro-enterostomy disclosed adhesions between the pylorus and liver, some of which were broken down. A spastic ileus of the small intestines was also present, the large intestine being slightly distended, no cause for which was found. Death occurred early the next morning.

Wound autopsy by Dr. Libman. The stomach was moderately dilated and a large ulcer was found on the posterior wall at the pylorus. The ulcer had a very sharp edge. The greater portion of the ulcer extended through the stomach wall, a part of the floor being made up of the pancreas covered with inflammatory tissue, and part by the left lobe of the liver. The edge of the ulcer at the last mentioned place was very thick and looked carcinomatous. (Microscopical examination showed only the evidence of acute inflammation). There were adhesions between the stomach, colon, liver, ascending colon and between the loops of the small intestine. The stomach otherwise showed the lesions of an acute gastritis. Liver and spleen negative; beginning congestion. The upper part of the small intestine was moderately dilated. In the middle third was a contracted portion about 30 cm. long, but this did not present the appearance of a spastic ileus.

3. PYLORIC STENOSIS.

Among the cases of stenosis of the pylorus the following deserve particular notice.

Case VIII. Benign Pyloric Stenosis Secondary to Gastric Ulcer; Pulmonary Tuberculosis; Finney Operation; Recovery.—Max S., Russian, forty years of age, peddler, was admitted May 21, 1903. Family history and previous history negative.

Present history of three years' duration, beginning with pressure in the epigastrium and occasional vomiting, not bloody. For the past six months vomiting daily, especially at night, large amounts of mucus and food; no blood. For the same length of time has had attacks of abdominal cramps, not radiating, two or three hours after each meal. Bowels constipated.

Physical examination showed signs of tuberculosis in apices. Sputum contained tubercle bacilli. Otherwise examination was negative except that there was a large splashing stomach which extended to just below the umbilicus; palpation was negative; no increased peristalsis. Average of test meals: Total acidity 84, free hydrochloric acid 60; no blood. Delayed motility; capacity of stomach 2,000 c.c.

As all the local treatment had failed to give any relief in spite of daily stomach washing, and as the patient was rapidly losing weight both from inanition and the extension of the tuberculous process in the lungs, operation was decided on and he was transferred to the services of Dr. Lilienthal, who, on May 23, performed the Finney operation.

The stomach was found much dilated with considerable thickness in the pyloric region on the posterior surface. The mass did not feel cancerous but more like a cicatrizing ulcer. On the anterior surface of the pylorus were a few small spots in which the peritoneum was opaque; also one small yellowish tubercle. For twenty-four hours after operation vomited repeatedly, vomitus containing blood.

May 31.—To-day was placed on soft diet. No vomiting for several days.

June 13.—Wound healed. Discharged cured. No vomiting; no gastric disturbance. Patient gaining in weight.

The patient's total gain in weight was forty pounds and when seen some months afterward his general condition was excellent, and the tuberculous process in both lungs showed very decided improvement.

The association of tuberculosis with ulcer of the stomach is by no means infrequent. In some cases, as in the present one, the progress of the disease is very much hastened by the inanition which results from the incessant vomiting. That so brilliant a result should have been accomplished in this case was scarcely to have been expected since the patient's general condition at the time of operation was quite miserable. Almost a year has elapsed since the operation and the improvement in his condition still continues.

Case IX. Benign Stricture of the Pylorus, Secondary to Ulcer of the Stomach Associated with Hematemesis and Severe Pain Which Did Not Yield to any Treatment; Finney Operation; Prompt and Satisfactory Cure.[1]—Mary W., twenty years old, admitted February 24, 1902.

[1] Mt. Sinai Hospital Reports, Vol. III, p. 368.

During three years prior to operation there had been epigastric pain after eating. This pain became more severe five weeks before admission, and vomiting then set in. Within three days of her admission patient had two severe attacks of hematemesis. For three weeks after admission patient was fed exclusively on nutrient enemata. During this time there was marked improvement in the general condition. On April 3 the vomiting recurred and hemin crystals were found in the vomitus. Following this there were several attacks of pain and vomiting, and on April 12 there was an attack of severe pain in the epigastrium and right hypochondrium, radiating to the back. A few days later vomiting recurred and icterus was noticed for the first time. A trace of bile was found in the urine. The pain and vomiting continued, and the icterus became more marked, so the case was transferred to the surgical division.

The chemism was as follows: Test breakfast on March 26: 100 c.c.; well digested; total acidity, 78; free hydrochloric acid, 28; combined, 42; starch digestion much delayed.

March 27, 180 c.c. obtained; total acidity, 58; free hydrochloric acid, 36; combined, 30.

March 28, while fasting, through the tube 30 c.c. clear fluid obtained with high hydrochloric acid (60).

On April 26 pyloroplasty was done by Dr. Lilienthal, according to Finney's method. An incision was made in the right hypochondrium through the rectus. Gall-bladder and ducts were found normal. The stomach was dilated. The pylorus just admitted the tip of the little finger; nothing else abnormal was found except an indurated area on lesser curvature near the pylorus, evidently on old ulcer. The pyloroplasty was done with silk Lembert sutures inserted between the stomach and duodenum. When these sutures were tied, stomach and duodenum were united from pylorus to a point about four inches from pylorus. A second row of Lembert mattress sutures was inserted but not tied, this second row being parallel with the first row and about three-quarters of an inch from it. A curved incision, like an inverted U, was then made from a point between the ends of the two rows of sutures into the stomach, thence parallel and between the rows of sutures through the pylorus, and down the duodenum to a point opposite the place of beginning. The first row of sutures was then reinforced by through-and-through sutures fastening stomach securely to gut, and then the second row was tied and reinforced (Finney's operation). A small drain was left in and the abdominal wound sutured. Uneventful recovery. Discharged cured May 17 and has remained so.

The next is another case of benign pyloric stenosis secondary to ulcer in which the Finney operation gave very satisfactory results, but which a number of months later was followed by a return of hematemesis from the probable formation of a fresh ulcer.

Case X. Benign Pyloric Stenosis Secondary to Ulcer of the Stomach; Finney Operation; Recovery.—R. L., Russian, aged forty-four years, housewife, was admitted February 19, 1903. She has been ill four years and in bed three months. Her illness began with copious vomitings, bearing no relation to the ingestion of food. The vomiting has increased and for the past year she has subsisted only on fluids. Two years ago, in addition to constant abdominal pain, the patient experienced sharp, piercing pain coming in paroxysms and radiating to the shoulder. These were very severe, resembling those of labor, and caused the patient to double up and cry out. The last attack occurred three weeks ago. These attacks are not accompanied by vomiting. There has been marked loss of flesh and strength.

Physical examination of the abdomen was impossible since the rigidity was extreme.

Test meal, ℥xii; total acidity, 80; free hydrochloric acid, 58; no blood. Distension of stomach showed marked dilation. Treatment: Lavage and antacids.

February 26.—Test meal, ℥xii; total acidity, 45; free hydrochloric acid, 26; no blood. Length of tube introduced to obtain stomach contents, 21 inches. Capacity of stomach, two quarts.

February 28.—test meal, ℥xxviii; total acidity, 122; free hydrochloric acid, 75.

March 2.—Patient on daily lavage. Still complains of pain.

March 5.—On rectal feeding; pain continues. ℥iv stomach contents in the average quantity obtained in several examinations of the empty stomach. The fluid contained quantities of hydrochloric acid and food particles.

March 11.—Test meal, ℥x; total acidity, 38; free hydrochloric acid, 16.

March 12.—Gaining weight under combined mouth and rectal feeding. Abdominal pains much less severe. Stomach washing every morning contains less residue than at beginning.

March 23.—Gastric measurements:

	Undilated.	Dilated.
Mid line above umbilicus . .	9.5 cm.	9.5 cm.
Mid line below umbilicus .	4.5	6.5
Mid line right umbilicus . .	7.5	9.75
Mid line left umbilicus . .	7.5	10.5

The temporary improvement which was above noted did not last long; on the contrary, the patient's pain and the vomiting returned, necessitating rectal feeding. In spite of this the patient's general condition did not improve and she was transferred to the surgical service of Dr. Lilienthal, who, on April 7, performed the Finney operation.

At the operation a benign stenosis of the pylorus was found secondary to gastric ulcer on the posterior wall. Convalescence was uneventful and she was discharged April 30, 1903, very much improved, having gained considerably in weight, free from vomiting but still complaining

occasionally of abdominal pain. On October 13, 1903, she was readmitted. The present history is that after having been very comfortable with the exception of occasional nausea and epigastric pain, which, however, is much less than before the operation, she began a week ago to complain of anorexia and vomiting which was independent of eating. There was also pain in the abdomen and back. Her chief complaint, however, was the vomiting which contained blood.

Physical examination was entirely negative. Examination of the stomach shows a capacity of 1,800 c.c. and no evidence of dilatation. Total acidity 58, free hydrochloric acid 20. Further tests were rendered impossible, since there has been daily vomiting of dark, coffe-ground material. Rectal feeding with excellent results and she was discharged cured on November 9.

4. PERIGASTRITIS.

There is no more striking proof of the great strides which have been made in the diagnosis and treatment of gastric disorders, than has been shown in the recent work on gastric adhesions, *i.e.*, perigastritis. For most of our knowledge of this subject we are indebted to the surgeons, and if the *furor operandi* on the stomach extends to much greater length, we will probably learn much more about perigastritis. That so little stress has been laid upon the clinical relations of perigastritis is all the more surprising since, as is well known, five per cent. of all autopsies shows gastric ulcers or their scars, and according to Soltau Fenwick, in 40 per cent. of these stomachs there are adhesions.

The clinical relations of these adhesions are most important, and the debt we owe surgery in the relief given to many of these cases is no small one—provided, of course, that the future does not show that the new adhesions which form after the operation do not in turn produce symptoms.

Fenwick [1] has classified 123 cases of gastric ulcer with adhesions. The figures are instructive.

Organ.	No. of Cases Adherent.	Per Cent.	
Pancreas (alone)	49	40	74.9
Liver (alone)	33	26.8	
Pancreas and Liver	10	8.1	
Colon	7	5.7	
Liver and Colon	4	3.2	
Spleen	2	1.6	
Mesentery	3	2.4	
Three or more organs[2]	15	12.2	

As regards site all observers agree to the relative freedom of the anterior surface, the freer movement of which readily affording the explanation for its immunity.

In a recent report of 42 operations for perigastritis associated with gastric ulcer, Paton[3] has concisely reviewed the symptomatology. The leading feature is the chronicity of the symptoms which fail to yield to any plan of treatment, including the most stringent Leube cure. The pain and local tenderness may be often confined to one area, or it may be variable in this regard. The severity also varies; so do its relations to food, since the taking of food has less influence in causing pain than in simple ulcer. Posture and sudden exertion have greater effect. Vomiting is not so frequent in occurrence. Jaundice and other symptoms depend on the relation of the adhesions to the adjacent organs. Fasting has no effect on the pain or other symptoms—indeed, it is the failure of all plans of treatment that leads us to suspect the presence of adhesions.

Two cases of peripyloritis may be presented to illustrate some of the clinical phases. The results of the surgical treatment of Case XII also demonstrates that the subsequent course may warrant conservatism in the prognosis.

Case XI. Ulcer of Stomach; Peripyloritis; Exploratory Operation; Recovery.—Annie S., thirty-three years of age, German, admitted October 25, 1902, with the history that eight months ago she had an attack like the present one with pain in the epigastrium after eating and relieved by vomiting. At this time she had hematemesis and was in the German Hospital for four weeks. Her present illness is of two weeks' duration. There has been a constant feeling of weight in the epigastrium and sharp pains over the stomach, radiating laterally to either side and through the back, after meals. An hour after eating there is vomiting with relief of the pain. The vomitus consists of black coffee-ground material followed by the digested food. Vomiting is preceded by nausea. Anorexia present. Bowels constipated. Stools firm, black and contain blood.

Physical examination: Stomach not enlarged to percussion. Some tenderness to the right of the median line two fingers below the ensiform. The tube was not introduced. Patient put on rectal feeding.

October 27.—Has not vomited since admission. Pain less severe; tenderness slight.

November 9.—Yesterday patient complained of pain and vomited; severe epigastric tenderness. About two fingers above the umbilicus and in the median line, a small body is to be felt the size of a chestnut, just to the right of the aorta. It lies transversely at the level of the eighth costal cartilage and can be felt under the right rectus.

Test meal: ℥ii well digested. Total acidity 36, free hydrochloric acid 10.

November 13.—Test meal: ℥iii, well digested. Total acidity 56, free hydrochloric acid 26.

As the patient's symptoms persisted in spite of treatment and as she was rapidly losing weight, she was seen by Dr. Gerster, who advised operation.

November 17.—Exploratory laparotomy was done by Dr. Gerster. The operation revealed a healing ulcer of the pylorus with a peripyloritis.

1 Ulcer of Stomach and Duodenum, 1900, p. 29.
2 Including pancreas, liver, diaphragm, abdominal wall, colon, spleen, omentum, mesentery, kidney and right adrenal.
3 Lancet, Feb. 6, 1904.

No gastro-enterostomy was done, the operation being simply exploratory. Subsequent to the operation all symptoms disappeared and she was discharged cured on December 12.

How much the operation contributed to the patient's recovery must remain an open question. In fact, in view of the findings its value may well be questioned, yet the patient's condition and the presence of the suspicious mass above mentioned made the indications for it seem justifiable.

The following case, a fatal one, of gastric ulcer, peripyloritis and diffuse adhesive peritonitis presents some peculiar and unique features.

Case XII. Gastric Ulcer; Peripyloritis; Posterior Gastro-enterostomy; Entero-enterostomy; Recovery; Subsequent Persistent Vomiting from Formation of Extensive Peritoneal Adhesions; Laparotomy; Division of Adhesions; Recovery; Reformation of Adhesions Causing Recurrence of Vomiting; Laparotomy; Death.[1]—Betsy B., twenty-two years of age, had been operated upon in Vienna for some gastric trouble two and one-half years before. After the operation she was fed through a gastrostomy (?) wound for five months, when the opening into the stomach was closed by suture. She left the hospital in Vienna feeling well, and remained so for one year. Five weeks before admission she was seized with epigastric pain radiating to right side and back. For the last twelve days she vomited everything she ate or drank. There was no pain after eating, but almost immediate nausea and vomiting. No hematemesis. No blood in stools. Several chills occurring with attacks of severe pain. On admission, January 29, 1902, there was a laparotomy scar in epigastrium; exquisite tenderness over pylorus, where a mass of adhesions (?) was to be felt. Stomach by percussion was dilated upward. On administering milk it was returned within thirty seconds, coagulated and acid. Stomach tube was easily passed through the cardia.

January 30.—Patient vomited fresh blood, and again on January 31 she vomited two ounces of fresh blood.

For a week she was fed exclusively per rectum. Pain and vomiting continued. Temperatures between 99° and 100.8° F., pulse rate 70 to 90. Urine contained a trace of albumin, no casts. White blood cells, 10,300.

February 7.—Transferred to Dr. Gerster's service for operation. Laparotomy for gastric ulcer and peripyloritis. Incision through scar of previous operation. Numerous firm adhesions between intestines, and especially between the under surface of the liver, gall-bladder and pylorus. Though evidences of healed pyloric ulcers were visible, no recent ulcer could be located. The pylorus was much injected. The jejunum was firmly adherent to abdominal parietes, from which it was inferred that at the previous operation a jejunostomy had been performed. In prolonging the incision downward the adherent loop of jejunum was incised. It was at once freed and the rent repaired. This narrowed the lumen of the segment very materially. After further seperation of adhesions, a posterior gastro-enterostomy with Murphy's button was established, and in order to overcome the narrowed loop of jejunum an entero-enterostomy was performed, this excluding this loop of intestine. Through-and-through abdominal sutures. Drainage. The patient, though in very wretched condition, bore the operation nicely. She vomited a bile-stained fluid for several days, but after repeated lavage this ceased. The wound healed slowly; several stitch holes became infected.

February 22.—Patient was out of bed; felt well; no pain; no vomiting; takes solid food; had not passed the buttons. She remained well until March 9, when she again commenced to vomit.

March 11.—Passed one button (thirty-second day).

March 19 to 25.—Vomited at times; general condition good.

March 27.—Vomiting very frequently—large amounts of greenish material. Patient was rapidly losing ground. On this account it was decided to reopen the abdomen, supposing that either a contraction of the gastro-enteric orifice or an impaction of the Murphy button was the cause of the persistent vomiting.

March 28.—Laparotomy for postoperative adhesions. Incision through old scar. Numerous intimate adhesions were encountered, matting together into an intricate mass the small intestines and stomach. The separation of these adhesions was cautiously done, but nevertheless a loop of jejunum was incised. Immediate repair. Examination of the gastro-enteric anastomosis showed no impacted button, nor could the button be felt in the stomach. The orifice was not contracted, easily admitting two fingers. The entero-enteric anastomosis was likewise firm and its orifice adequate. The button was not impacted. The loop of jejunum which had been incised at the previous operation, and doubts of whose sufficient patency were had at the time, was examined and found to be of adequately large lumen. The loops of ileum were much contracted, whereas the jejunum was distended. After freeing all adhesions the lower coils of small intestines became distended. It was therefore presumed that the adhesions were the cause of the vomiting, and after a further unsuccessful search for the button the intestines were replaced and the abdomen closed.

April 1.—Again the patient vomited for several days, but this stopped and immediately she commenced to gain flesh and strength.

April 21.—She developed mastoid disease, necessitating opening of mastoid.

May 16.—Vomiting again; which gradually became more frequent until she could retain no food. Gastric lavage did not check the vomiting. Rapidly failing in strength.

May 22.—Repeated vomiting and poor condi-

[1] Mt. Sinai Hospital Reports, Vol. III, p. 197.

tion necessitated a third interference. Incision through old scar. Findings were practically identical with those at the previous operation; dense intimate adhesions of all the intestinal coils to each other. The lower portion of the ileum was collapsed; the upper loops of jejenum were in part collapsed and in part distended. Numerous kinks due to adhesions were straightened out. The adhesions were separated; they were too extensive to permit of being covered with Cargile membrane. The intestine below the entero-anastomosis was fixed into the abdominal wound so as to enable the patient to be fed through a jejunum fistula, if this was necessary. Closure of rest of wound. Vomiting persisted and did not subside after lavage.

May 23.—The intestine in the wound was opened, but a catheter could not be passed into it a sufficient distance to enable nourishment to be given in this way. Vomiting continued.

May 24.—During an attack of vomiting the small intestines were crowded out of the lower angle of the wound. They were immediately replaced. Soon after this the patient collapsed and died—a most sorrowful termination after so much heroic courage and suffering.

SYMPTOMATOLOGY AND COURSE OF GASTRIC ULCER.[1]

BY MAX EINHORN, M.D.,
OF NEW YORK;
PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

It is well known that the symptoms of gastric ulcer are quite manifold. In a number of instances there are no outward manifestations of an existing ulcer, until accidentally discovered at a laparotomy or by the appearance of a hemorrhage.

S. Fenwick and W. S. Fenwick[2] make a distinction betwen acute and chronic ulcer of the stomach. But taking into consideration the possibility of a latent period of an ulcer, we are never sure when its existence began. The acuteness of the symptoms does not necessarily mark the beginning of the disease. For this reason it appears to me that from our present knowledge we are not warranted in subdividing clinically a group of acute ulcer of the stomach.

The symptoms ordinarily met with in gastric ulcer are the following:

1. *Pains.*—Patient experiences pain in the epigastric region shortly after meals. The pain is generally more pronounced after eating coarse articles of food, and is occasionally also felt at the left side of the back (in the lumbar region). The same areas (epigastric and left lumbar region) are likewise tender as a rule, or, more correctly, painful to pressure. It is characteristic of this affection that even moderate or slight pressure produces a painful sensation. In rare instances, however, this symptom is lacking.

2. *Vomiting.*—Regurgitation of part of the food and vomiting half an hour to one to two hours after meals is frequently met with. If present, however, it does not necessarily form a constant phenomenon, and may appear for a few days in succession off and on. Both the regurgitation and the vomiting are preceded by attacks of pain, which are usually relieved by the emptying of the organ.

3. *Hemorrhage.*—Hemorrhages from the site of the lesion frequently take place. If small, however, they often escape detection. When moderate or of considerable size they are seldom overlooked, for they then generally give rise to hematemesis or melena, or to both.

Blood, if present in sufficient quantity, is easily recognized in the vomited matter, or in the dejecta, by its appearance (red, coffee-brown, and tarry). When, however, the macroscopical appearance does not betray its presence, Weber's[1] test may frequently reveal it. This test is executed as follows: The fluid to be examined is mixed with a few cubic centimeters of glacial acetic acid and thoroughly shaken with sulphuric ether. The ethereal extract presents a Tokay-wine color if blood be present. If the color is not distinct, add to the ethereal extract equal parts of freshly prepared tincture of guaiacum and ozonized oil of turpentine which produce a blue color in the presence of hemoglobin.

Recently Boas[2] and following him Hartmann[3] and others have advocated the examination of the gastric contents and of the feces by means of Weber's test, in order to discover these so-called concealed hemorrhages. In a number of cases of ulcer of the stomach these small hemorrhages can thus be discovered from time to time by examining the vomitus or the stool, according to Weber.

It is important to know, with regard to this test, that raw meat and, according to Hartmann, even boiled meat is apt to give the reaction, even if there be no hemorrhage. For this reason meats must be eliminated from the diet for a few days previous to making Weber's test.

The symptoms accompanying a profuse gastric hemorrhage are principally those caused by the loss of blood and are similar to those encountered in any acute hemorrhage (pallor, giddiness, weakness, fainting spells, extreme thirst). Occasionally there is a rise of temperature present for a few days.

4. *Appetite.*—The appetite is as a rule not impaired. The patient, however, takes very little food on account of the pain.

5. *Cachexia.*—The general state of nutrition of the body is sometimes good, especially if the

ulcer is not of very long standing. When the latter, however, has lasted a very long time cachexia is almost always present.

It is self-understood that the above symptoms need not all exist at the same time. Sometimes one symptom (vomiting, pain) is constantly present and forms the main feature of the disease. Now and again one certain symptom alternates with another.

Gastric Functions.—Gastric secretion is frequently increased in quality (hyperchlorhydria) as well as in quantity (hypersecretion). A number of cases, however, go along with a normal gastric juice and a few with a diminution or total absence of the same.

The motor function is generally normal, excepting when the ulcer involves the pyloric region or its vicinity. In the latter instance it is usually retarded. Sensibility is often increased, as evidenced by the pains after the ingestion of food. Hydrochloric acid in weak solutions, and other irritating substances, produce pains in the stomach soon after their administration. Orthoform, as shown by F. H. Murdoch, or still better anesthesin, frequently allay the pain, as they serve as a local anesthetic. Large doses of subnitrate of bismuth act in a similar manner, forming a cover over the affected area.

Course.—Gastric ulcer sometimes heals spontaneously by cicatrization. In the majority of cases the healing process does not go on so easily. Favorable conditions must first be created before a cure is possiblbe. Rest of the entire organism and principally of the stomach is here of the greatest importance. In most instances an abatement of the symptoms takes place, and in a great many instances a real cure is established. In some the ulcer remains open and soon gives rise to a new outburst of symptoms. But a few cases show no tendency whatever to heal, and the patient may succumb to hemorrhages, perforation, or to the inability to take food, resulting in consecutive starvation.

Ulcers near or within the pylorus are much slower in healing and frequently cause continuous hypersecretion with or without ischochymia. They are difficult to manage and often require surgical aid (gastro-enterostomy) in order to make a cure possible.

Russell[1] has tried to investigate the after-history of cases of gastric ulcer with hemorrhage. The result of his inquiry was as follows: The direct mortality from the disorder has amounted to 2.1 per cent., 4.3 per cent. have died from intercurrent disease, 42.6 per cent. have ended in recovery—27.7 per cent. having had but a single attack and 14.9 per cent. having recovered after one or more relapses; 6.4 per cent. cannot as yet be classified; they appear to be on the border line between recovery and continuance of the disorder, and will eventually fall into either class. Finally, 44.7 per cent. were suffering from stomach symptoms of more or less severity at the time of the last report, 14.9 per cent. getting repeated and definite attacks, with intervals of immunity and 29.8 per cent. suffering from almost continuous pain.

This report of Russell is quite discouraging; a similar view is entertained by Debove[1], for he gives the following figures for 100 cases of ulcer:

Perfect cure	50
Perforations and peritonitis	15
Foudroyant hematemesis	5
Pulmonary tuberculosis	20
Inanition	5
Different complications	7

My own experience is, however, decidedly more favorable. I have seen a much larger percentage of seemingly permanent recoveries than that given by either Russell or Debove. It may be that the way the patients live after the cure has much to do with their future. Those leading a rational life, avoiding too coarse foods and violent exercises have a greater chance of remaining well than those who cannot have the much desired care. This would easily explain the larger percentage of the recurrence of the disease in Russell's patients, who were hospital cases and belonged to the poorer class, often unable to heed the necessary dietetic rules.

FURTHER REMARKS ON ORTHOFORM IN THE DIAGNOSES OF GASTRIC ULCER.[2]

BY FRANK H. MURDOCH, M.D.,
OF PITTSBURG, PA.

Two years ago, I presented a paper at a meeting of this Association, entitled "Orthoform in the Diagnosis of Gastric Ulcer." Since that time I have seen three additional cases in which this remedy was of great value in differentiating gastric ulcer from other painful affections of the epigastrium.

Case I.—July 3, 1903, Mr. M., aged sixty years, bookkeeper, consulted me, and gave the following history: In February, 1901, that is a year and a half before he came to me, he had a severe attack of pain in his abdomen, which was of such severity that a hypodermic injection of morphine was necessary to relieve it. After this attack he complained of pain and soreness in the the right iliac region; and the attending physician, suspecting appendicitis, called in a surgeon, who decided that his appendix was in a healthy condition, and therefore not responsible for the previous attack of pain. In May, 1902, and again in May, 1903, he had an attack similar to the first, and in both instances had morphine hypodermically to relieve him. After each attack he remained in bed and lived on liquid food for two or three weeks.

Present Condition.—He looks rather pale, has lost five pounds in weight. Appetite good, bowels

2 Read at a meeting of the American Gastro-enterological Association, in Atlantic City, June 6, 1904.

constipated, sleeps well. Physical examination is negative, excepting that there is one very sensitive spot in his epigastrium. Examination of the stomach contents showed that free hydrochloric acid was absent, rennet and pepsin present. The diagnosis was chronic gastric ulcer with resulting gastralgia. He was due at my office in the afternoon of the next day, to receive directions as to diet, etc., but instead of coming to see me, he sent for me in haste, as he was having another attack of pain. I found him suffering intensely, but instead of giving him a hypodermic injection of morphine I administered eight grains of orthoform, and in twenty minutes he experienced entire relief.

Case, II.—Mrs. A., aged thirty-eight years. Consulted me November 29, 1902. When fifteen years of age she had an attack of stomach trouble which lasted two months. She complained of bloating and belching, and much distress after meals, relieved by vomiting. After this attack she remained perfectly well for six years, at which time she was married, and soon after her marriage became pregnant. Two months after conception she was seized one morning with severe pain in the epigastrium, which was relieved at the end of two hours by an anodyne. During the last seven months of her pregnancy she had a severe attack of pain every week or two, relieved by vomiting. After her confinement, when the child was only seven days old, she had another attack; and has had them at longer or shorter intervals ever since, covering altogether a period of seventeen years. She has consulted many physicians, and the diagnosis usually made was biliary colic. Her appetite has always been good, her bowels constipated, moving only when she took a laxative. There was much gas in the stomach and transverse colon, and one circumscribed spot of great tenderness in her epigastrium. Free hydrochloric acid was present, Töpfer's test showing an acidity of 16; total acidity 60. The diagnosis was gastralgia the result of chronic gastric ulcer.

It was on Saturday that I first saw her, and she was directed to come in again on Monday for instructions as to diet, etc. On Sunday afternoon her husband telephoned me from a drug-store to say that she was having an attack of pain and was suffering intensely. I instructed the druggist to give him eight grains of orthoform, with directions to administer it to his wife as soon as he reached home, and I would call as soon as possible. In half an hour she was relieved.

Case III.—March 21, 1902, Mrs. McK., aged thirty years. Complaining of stomach trouble for twelve years. At first the attacks came on once or twice a year, lasting two or three weeks, and were characterized by distress after meals, with much bloating and belching. Gradually they became more frequent and more severe until for three years past there has been no period of relief except for a day or two at a time. Examination shows that there is a mitral presystolic murmur, the stomach is dilated, the lower border reaching three inches below the navel, the right kidney is in the third degree of displacement, and there is one very tender spot in the epigastric region and one to the left of the lower dorsal vertebræ.

Examination of the stomach contents after Ewald's test meal shows that free hydrochloric acid as well as the ferments are absent. Rennet zymogen is present. The diagnosis was chronic gastric ulcer, and the treatment rest in bed and liquid food. Treatment, however, had little effect in relieving her. The distress in her stomach, as well as the bloating and belching continued, so that at the end of two months there seemed to be little if any improvement in her condition, and the tenderness in the epigastrium persisted. Two physicians who saw her in consultation did not agree with me in the diagnosis, but attributed her symptoms to gastritis. On June 10, after she had been under treatment for nearly three months, she was suddenly seized one evening at eleven o'clock, with such severe pain in the epigastrium that a hypodermic injection of morphine was necessary to relieve her. I did not see her in the evening when the attack came on, but saw her next morning and directed orthoform to be given should the pain recur.

About noon of the same day a sharp pain began to shoot through from the tender spot in the epigastrium to the tender spot in the dorsal region, which lasted only for the fraction of a second, but was so severe as to cause her to cry out. At first this pain came on about every half hour, but gradually became more frequent until about ten o'clock in the evening there was an interval of only a few minutes between them. At eleven o'clock she took an orthoform powder, and in twenty minutes the pain ceased and she slept quietly until morning. The pain returned at six A.M. and at twelve noon; also at 1:30 A.M. and nine A.M. of the following day, but was promptly relieved by the remedy. She took altogether five powders. Each of the first four powders relieved her for about six hours. After the last powder there was no return of the pain.

The fact that orthoform so promptly relieved the pain in this case could leave no doubt as to the presence of an ulcer; *and it also showed that in spite of rest in bed and liquid food for nearly three months the ulcer still remained open.* This patient was in bed altogether four months and lived on liquid food for five months. She made a complete recovery.

Here, then, are three cases, in one of which appendicitis had been suspected; in another the usual diagnosis had been biliary colic; and in the third case a diagnosis of gastritis was made by at least two physicians. The correct diagnosis was established in each case by the administration of orthoform for as this remedy will not anesthetize nerve endings when they are protected by skin or mucous membrane, it is certain that if it relieves pain in the stomach it can do so only by coming in contact with a surface from which the mucous membrane has been removed.

TWO OLD FRIENDS: CASTOR OIL AND SALTS.

BY EDWARD P. CARLTON, B.SC., M.D.,
OF KEYESER, WIS.

Every physician, and especially a country physician, who dispenses his own medicines, has frequent occasion to observe the administration of either castor oil or magnesium sulphate.

Both have a disagreeable taste. The mere anticipation of a dose of either being enough to produce repugnance and nausea in many individuals. Children especially, soon learn to object strenuously to either.

Both castor oil and magnesium sulphate are inexpensive, and they have many desirable peculiarities not found in the other and more recent substitutes.

For some time I have been using large quantities of both castor oil and salts without any friction or bribery, and giving them continuously to delicate and sensitive patients, even without their knowledge of the fact.

Thinking that others might be interested in my formulæ, I give them below, without, however, claiming any great originality or ingenuity in preparation.

I.

Olei Ricini Dulcis.

℞ Vanillin,	gr.xx	1.5
Olei. menth. pip.,	℥j	4.0
Garantose (saccharin),	℥jss	4.0
Alcohol,	℥jii	100.0
Tinc. persionsis,	℥ss	15.0
Olei Ricini, q.s. ad. one-half gallon,		2000.0

Directions for Mixing.—Dissolve the vanillin, oil of peppermint and garantose in the alcohol. Add the tincture of cudbear to the oil and shake thoroughly. Finally unite the two mixtures.

This mixture keeps well, looks nice, is pleasant to take, does not leave a bad after-taste; requires no urging to get it down and, therefore, for all practical purposes, is a *disguised oil.*

II.

Liquor Magnesium Sulphatis Compositus.

Magnesii Sulphatis	℥xxxii	1000.0
Fluidi cardamomi comp.,	℥ii	30.0
Vanillin,	gr. xx	1.5
Garantose, "crest," Merck,	℥ii.-iv	8 to 16.0
Alcohol,	℥ii	60.0
Glycerin	℥ii	60.0
Coffee, roasted and ground,	℥ii	60.0
Aquæ q.s. ad. one-half gallon		2000.0

Directions for Mixing.—Stir the ground coffee in one-half gallon of boiling hot water, and allow it to stand for ten to twenty minutes. While this is still hot add enough of it to the magnesium sulphate to make about three and one-half pints. Dissolve the vanillin in the alcohol, add the glycerin to it and then the cardamom. When the first solution has cooled somewhat add the second mixture to it. After shaking thoroughly add the garantose ("crest")[1] and enough of the coffee infusion to make one-half gallon. Finally filter through a covered filter.

An ounce of this solution contains one-half an ounce of magnesium sulphate.

This solution keeps well, has a dark, whiskey-like color, a nutty odor and is easy to take, warm or cold. I dilute it with twice its volume of water at the time of administration.

[1] Heretofore I have used the plain garantose in alcoholic solution, but in the future I intend to use garantose "*Crest*" (Merck), which is soluble in water.

INTERNAL ANTISEPSIS.[1]

BY J. N. HALL, M.D.,
OF DENVER, COLORADO.

Until a few years ago the surgeon assumed the responsibility for most of the deaths from sepsis. The improvement in his methods of work has produced no more striking result than the almost total elimination of this term from the list of the causes of death of his patients, while the physician still signs a comparatively large number of certificates bearing this opprobrious designation. No more fertile field presents itself for our attention than this one. Fortunately we are encouraged by the recent general attention given to this subject by the profession, and by the favorable results which have attended, in small measure to be sure, some of the work along this line.

The more general use of the antitoxins, which I shall briefly mention in this paper, might at first sight appear to render unnecessary a struggle for a system of internal antisepsis. Yet when we consider that, for instance, a definite croupous pneumonia may be caused by many different organisms, and that, until bacterial examination becomes more available than it now is in clinical examination, we shall be unable to administer the right antitoxin even if we have it, at the very beginning of the disease, as is so generally imperative if we look for good results, we must conclude that in this disease, as in many others, we shall long have opportunity for battles against a more or less general sepsis. We need not fear that our efforts will be wasted.

We assume that in all cases wherever possible surgical measures should be taken for the prevention of sepsis. It is vastly more scientific to drain an abscess than to attempt to treat a subsequent sepsis by medical measures. To the attainment of this better result where possible the physician may contribute by earlier diagnosis and the more prompt calling in of surgical aid.

But in those cases seen too late, or in which prevention, according to our present light, is out of the question, we must seek aid by means of medicines. As an example take typhoid fever, or sepsis of so-called cryptogenetic origin. Here treatment through the blood stream seems at present our only recourse.

An antiseptic in the laboratory must either prevent the growth of septic organisms, or destroy them. Their ability to do harm lies not so much

[1] Read before the American Therapeutic Society, June 3, 1904.

in the few which first enter the blood stream as in the capacity of these for indefinite multiplication. An infinitely less powerful antiseptic suffices to prevent reproduction than is necessary to cause the death of the parent organism. It is likely that more is to be accomplished by attempts to attain the former end than the latter. It is the newly-bred plasmodia of malarial fever which are killed by quinine rather than their progenitors. A step further and we should be able to prevent their propagation.

We may even conceive of such action of a drug that, while it did not interfere with the propagation of micro-organisms, might result in destroying their ability to develop their peculiar toxins. Although the opium-bearing poppy grows in England it is worthless for the production of its alkaloidal elements.

One of the most important fields for our study lies in the digestive tract, and here, thus far, the most important results have been accomplished.

Many digestive diseases result from failure of one of nature's agencies to do the work set for it. It is probable that we escape many serious infections owing to the antiseptic effect of the two parts per thousand of hydrochloric acid in our gastric juice, most notable among these being cholera. It is fairly established that in any reasonable numbers comma bacilli are unable to survive the acidulated bath which greets them upon entrance to the normal stomach. In the present light there seems little doubt that Pettenkofer, after the neutralization of his gastric juice with sodium bicarbonate, and the swallowing of a cholera culture, did actually suffer from cholera of mild degree. Nature, then, furnishes us the first example of internal antisepsis for our study.

The reported hyperacidity, as judged by human standards, of the digestive fluids of carrion-eating birds is a point deserving of attention. The millions of virulent organisms swallowed thus become harmless, although we must assume also a relative insusceptibility in these creatures.

It is probable that the long practised exhibition of hydrochloric acid in typhoid fever is really soundly based upon two foundations. It probably acts in part by improving nutrition through supplying a digestive ingredient lessened by the fever, thus promoting normal digestion; and in part by the prevention of growth of organisms of fermentation in the intestines of the subject weakened by the fever. The giving of this acid to those patients whom we so often see, suffering from flatulence because of imperfect gastric digestion, resultant inability of the intestine to do its portion of the work, and consequent development of fermentation and putrefaction in the starchy and other ingredients of the intestinal contents, is really a measure of antiseptic medication in its final result. Hammarsten states that "Putrefaction does not occur in the small intestine as long as the contents are strongly acid."

Wilcox and others have pointed out the mode of action of chlorine in typhoid fever in lessening the development of the causative bacillus and consequently of its toxins, in part at least by increasing the secretion of bile, and their results encourage us to still further study along this line. Yet the recent total collapse of a proposed antiseptic treatment of this disease when put to the actual test in the wards of a great Government Hospital is fresh in our minds. It had received wide attention because of a specious plausibility. Yet the results were what a sound thinker might expect in view of the almost total disregard of the pathological aspects of typhoid fever. It may be that we shall be able to influence in a measure the symptoms arising from the absorption of the toxins of the bacillus of Eberth, but we must not forget that often the bacilli are established in the spleen and mesenteric glands, in the lung or even the meninges, and we must at least consider these things in our scheme of treatment. We shall scarcely cure a typhoid meningitis by the exhibition of intestinal antiseptics.

A word of caution against the too strenuous use of these remedies, for we should at least beware of doing harm. I have recently seen a well marked case of acute nephritis resulting from the too free use of salol in the treatment of a moderately severe attack of typhoid fever. The urine had the appearance of that so familiar to those of us who were in hospitals in the days of the free use of carbolic acid as a surgical antiseptic. Other similar examples have come to my notice, and I doubt not to that of most of those present, from this and other internal antiseptics.

There seems to be no especial ground for fear that we shall interfere seriously with digestion by destruction of bacterial life in the intestinal canal. Bacteria do not seem essential to digestion, for Levin found that the intestinal contents of many Arctic animals, birds and fishes were practically sterile. Although we may accomplish much by use of various bismuth compounds, naphthalin, salicylic acid and other remedies, no generally accepted intestinal antiseptic has been brought forward.

The observations of Bouchard show the diminution of the number of pathogenic bacteria in the feces under the use of naphthol, while Hueppe "found that no cultures could be made from the intestinal contents of a patient who had died from apoplexy supervening during asiatic cholera, and who had been treated by bismuth tribromophenolate exclusively." Progress is being made yearly along these lines.

In the urinary tract we have been more successful in the application of antiseptics to combat bacterial infection. In cystitis, pyelitis and pyelonephritis the results of treatment are now far better than under the former mode of administration of diluents and demulcents. The recognition of the typhoid bacillus in the urine has led to systematic attempts by the use of urotropin

and other antiseptics, to prevent its excretion in the urine. So far as this single feature is concerned I submit that it is better to avoid dissemination of typhoid by destruction of the bacilli after their passage than to attempt their destruction in the body of the sick man. The use of such antiseptics, however, is justifiable for the avoidance of typhoid pyelitis and similar infections. Richardson, Andrews and others have demonstrated the entire disappearance of the typhoid bacilli from the urine under the administration of hexamethylenetetramin. In almost all cases where we have reason to fear a destructive process in the kidneys, or an ascending infection, such treatment is imperative and the results are most gratifying.

A few years ago I was much interested in the study of certain infections of the urinary tract caused by the colon bacillus. Several of these cases progressed to a fatal end, and at postmortem examination exhibited abscess formation in the most various localities. In others to whom urotropin was administered early and in sufficient amount, the urine gradually cleared and recovery resulted. I believe that in these cases we have the most brilliant examples of the influence of antiseptics given internally that have fallen under my observation.

In one of these cases following gonorrhea the colon bacilli in the urine could be noted to decrease with the increase of the dose of urotropin, until, when a total somewhat exceeding the usual maximum dosage was given, the urine remained clear. A decrease of the dosage was followed by the reappearance of the acid, cloudy and ill smelling urine so characteristic of the condition. These facts I had the privilege of verifying by study of the case with Dr. Leonard Freeman.

This patient some four years afterward died of accident, and I had the opportunity of examining the kidneys. In spite of the prolonged general infection of the urinary tract, and most serious systematic infection as well, no traces of the trouble were to be found.

In two patients who had glycosuria the results of the infection were fatal, while in three others recovery took place. I believe that the unusually favorable opportunities for growth of the *Bacillus coli* in the diabetic subjects, with their well known lack of resisting power, turned the scale adversely in the attempt to inhibit the growth of the organism by the exhibition of the urinary antiseptic. There is great ground for hope that we may yet find an intestinal antiseptic as generally useful against infection of the digestive tract as is this drug in urinary infections.

Until bacteriologists give us more positive evidence as to whether acute articular rheumatism is of definite bacterial origin or not, speculation as to the cause of the improvement in these cases from the giving of salicylates is idle. There is not sufficient evidence as yet to establish a presumption that the good effects come from any antiseptic action. As regards the treatment of syphilis by mercury, practically the same conclusion may be offered.

One phase of the supposed etiology and the treatment of pernicious anemia deserves a brief mention. The theory has been advanced that the disease results from the swallowing of pus-producing organisms, especially in those suffering from pyorrhea alveolaris, and that arsenic cures by its antibacterial effect in the digestive tract. Two cases of this disease, which failed to improve under the usual treatment by mouth, I have recently treated by hypodermatic adminstration of cacodylate of soda, with immediate benefit. The very fact that the cases improved so promptly under this treatment suggests that the theory of direct intestinal antiseptic effect of the arsenic can not be sustained.

The effect of creosote and its congeners upon the bacilli of tuberculosis, as shown by repeated examinations of the sputum during the treatment, is generally believed to be a fairly definite one, for Holscher, Axtell and others have shown their gradual decrease in certain cases. Doubtless the results would be more easily noted were cases more generally placed under such treatment before the bacilli became abundant, and especially before mixed infection became a factor. The drugs act by rendering the soil unsuitable as a culture ground, and not directly as germicides.

In the treatment of pulmonary tuberculosis nothing is more discouraging than the sepsis which follows the introduction, almost certain to occur sooner or later, of pus-producing organisms into the pulmonic lesions. In the Denver City and County Hospital, a few years ago, Dr. Henry Sewall gathered together, from his own service and from mine, a large number of consumptives with mixed infection and treated them continuously, with my cooperation, with antistreptococcic serum. No sufficient results were obtained to lead us to continue the treatment.

In the case of a physician recently seen with Dr. Geo. A. Moleen, there were all of the clinical signs and symptoms of pulmonary tuberculosis excepting the absolute absence on repeated examination by different bacteriologists, of the bacillus of Koch, and the presence of innumerable streptococci. The use of streptococcic serum from a well known American firm, after less than a dozen injections, has resulted in the almost complete disappearance of the streptococci. This case might be well termed one of "streptococcic consumption," and the serum was apparently of great benefit to the general condition of the patient through its specific effect upon the streptococcic element.

With Dr. O. M. Shere, in December, 1903, I saw a case resembling this one excepting that a moderate number of tubercle bacilli were found among a horde of streptococci in the sputum. The temperature rose daily to about 102° F., with corresponding pulse rate, and the patient was steadily losing ground. The injection of 10 c.c. daily of antistreptococcic serum was followed in

five days by the almost total disappearance of the streptococci, and improvement in the local signs. In three weeks the temperature became normal, and has remained so. The young man has gained 12½ pounds. The tubercle bacilli have become much fewer in the sputum, taking the average of many slides. Whether the remedy is to receive all the credit for the improvement in these two cases or not, the results must lead us to study this method of combating sespis with the greatest hopefulness.

Dr. S. G. Bonney and others have reported similar improvement in certain cases, although in most instances failure to materially influence the progress of the disease has been reported.

With Dr E. P. Hershey I treated six cases of pulmonary tuberculosis with intravenous injections of dilute formaldehyde solution. They were extremely painful, but produced no visible serious results. Unfortunately they seemed to be without any obvious good results. No exact blood studies of these cases were made. The reported results of similar attempts in the treatment of sepsis by various authors were negative, some of the animals even dying before the controls did. It is obvious that a more effective and less troublesome antiseptic for this use is needed.

I have treated many cases of pneumonia with creosotal, but have seen no such constant and positive effect as to be worthy of record. Yet we have the most positive statements of Thompson and others in favor of the treatment—a sufficient justification of further trial. Practically the same statements hold good as to the use of sodium salicylate in this disease.

A distinct advance has been made in the introduction of colloidal silver and other silver preparations in the treatment of various septic conditions.

In six cases of the mixed infection of advanced tuberculosis, in the Denver City and County Hospital, with the cooperation of Dr. A. Freudenthal, we tried the effect of intravenous injections of collargol. One per cent. of the drug was dissolved in normal salt solution, and 90 to 120 minims were injected every second day. When the injection was made in the morning the evening temperature and pulse were lowered slightly as compared with the intervening days or those previous to the treatment. In a tuberculous empyema, the effect was rather more striking, a remission of 3° F. being noted at times. Still, the effect was so slight, and so devoid of apparent good effect upon the general condition that we did not continue the practice. It is possible that in the earlier stages of this mixed infection more positive effects might have been noted.

I believe that we may await with reasonable confidence the advent of some such internal antiseptic as shall measurably compare in effect in septicemia with that of the silver salts in gonorrheal ophthalmia. The weight of evidence is certainly in favor of the continued use of Credé's ointment in those cases of cellulitis, phlebitis and other inflammations caused by pus-forming organisms. Sufficiently favorable reports have been published to lead us to use such a line of treatment at least until something better is advanced.

Hume, basing his work upon the well-known leucocytosis of infection, and the increase in whites known to follow the intravenous injection of nitrate of silver, has sought to combat general infection by this means. He injected 500 c.c. of water containing .05 gram of silver nitrate. In ten cases of pyogenic infection there was but one death. No local results were observed excepting two cases of mild phlebitis. The theory is advanced that the treatment may do good by the destruction of red cells, and the setting free of antibodies. Inasmuch as several cases recovered in which the outlook seemed entirely desperate we should have no hesitation in commending a continuation of work along this line. In ulcerative endocarditis Robinson[1] states that "the treatment of the disease has now definitely in view the killing of the germs." He favors the early use of antistreptococcic serum perferably by the intravenous route, "because streptococci are undoubtedly among the organisms which appear frequently infiltrated, as it were, in the cardiac valves, at the autopsy in these cases. Powell reports three cases successfully treated in this way.

Sansom has used sulphocarbolate of soda in half dram doses "with such good effects that one patient was enabled to leave the hospital and remain away ten months before a fresh attack occurred." The diagnosis was confirmed after an attack which failed to yield to treatment, micrococci being found upon the valves.

Klotz narrates a case resulting successfully, in which colloidal silver was used hypodermically. After two injections there were rigors and no improvement; but after the third there was rapid decrease of fever and ultimate recovery.

Park and Payne recommended the use of salt solution intravenously as being less dangerous than formalin injections, and generally useful. It is possible, as pointed out by Netter, that the action of germicides in the blood is not due to their antiseptic effect, but to catalytic action. Possibly we are striving too much for mere germicidal power in our efforts to combat disease by intravenous medication.

Babcock believes that we should attempt to neutralize the toxins found in the intestinal tract in ulcerative endocarditis, believing that these, unless properly neutralized, aggravate the original disease. Robinson states that "the best and least harmful (antiseptics) which I have tried

1 I have drawn freely from Robinson's excellent article in the April number of the American Journal of the Medical Sciences.

are small, repeated doses of beechwood creosote, the salts of bismuth, and wood charcoal."

This review of some of the advances of the past decade in internal antisepsis leads us to look confidently for longer strides forward in the near future.

MEDICAL PROGRESS.

SURGERY.

Lingual Goiter.—Variations from the normal are most frequently seen upon or in the neighborhood of the median line of the body. HENRY R. STORRS (*Annals of Surgery*, Sept., 1904) presents an exhaustive article on the subject in which is included citation of all known cases. It is stated by Gruber that accessory thyroids are overwhelmingly more frequent in men than in women and yet a study of the cases in which they have developed into tumors, to which the term "lingual goiter" is given, shows that although the abnormality is so frequent in men and so rare in women, it is the women who almost always suffer from hypertrophy of the growth. There is no known explanation for this, but the fact that sex appears to be a predominating influence in this small and rare type of goiter, may be of great use ultimately in ferreting out the etiology of the general disorder known as goiter. Another important characteristic of the growth is its sudden development. It is usually well known that the patient has an accessory thyroid, but very frequently it gives rise to no trouble whatsoever. Suddenly, without any apparent reason, the growth leaps into great vascular activity and develops to such an extent as to require immediate removal. The pathological anatomy of the tumors is as follows: They are situated upon the dorsum of the tongue just behind and below the foramen cecum, but sometimes, as in Bernay's case, enclosing it. They are invariably round and their volume varies from the size of a cherry to that of a man's fist. Encapsulation is generally distinct and there is usually a freedom from inflammatory reaction in the neighborhood of the growth. It is smooth and shining and darker than the surrounding mucous membrane on account of the extraordinary vascularity of the growth. The vessels are found not only upon the surface, but they penetrate through and through the tissue and are certain to cause troublesome hemorrhage at the time of operation. This vascularity is one of the most important differential points in distinguishing the growth from dermoid. The tumor may or may not be movable, for this factor depends entirely upon the degree of involvement of the muscles of the tongue. The subjective symptoms are usually quite characteristic. They are almost invariably of such nature as to acquaint the patient with the existence of the growth without causing her sufficient annoyance to call for its removal. Then, of a sudden, voice changes occur and prolonged fits of coughing accompanied by deglutition spasms. Even though the tumor may be of large size, a laryngoscope may be necessary for differential diagnosis. The most important point to be determined is whether or not the growth is malignant. Sarcoma is usually even more rapid in growth and is painful. Carcinoma is not alone painful, but is almost always ulcerated. Lipoma is golden yellow. Gumma grows in a different manner. It ulcerates and is often multiple. Hypertrophy of the lingual is not very frequent. It is superficial only and consists of whitish yellow, hard concretions which distend the crypts of the lymph follicles and project from the surface of the tongue. Dermoid more closely resemble the growth than anything else, but they are characteristic by an absence of the latent period, which is almost always recognized in lingual goiter. The treament must be surgical, for medicines do no good. Puncture, as in the case of ordinary goiter is dangerous. The galvanocautery has been used, but its use has been more or less given up in favor of enucleation. This is preferably performed through the mouth, steady traction on the tongue controlling hemorrhage. The prognosis is good.

Treatment of Rectal Prolapse by Paraffin Injection.—Although a prominent practitioner of New York was recently sued by a woman for not having properly improved her looks by paraffin injections, the technic has undoubtedly achieved a very definite and assured position. Fortunately, in the case cited, the jury decided that the physician had improved her good looks, at least to the extent of the bill, and the case was dismissed. A. H. BURGESS (*Lancet*, September 10, 1904) records the history of 18 cases or rectal prolapse treated by injection. The paraffin which he has used, has a melting point of 111° F. The technic employed is as follows: The patient is anesthetized and the prolapse drawn out as far as possible. Around the margin of the prolapse, which are raised by reaction on three forceps placed at the apices of a triangle, the injection is begun. The needle is inserted into the middle of each side of the triangle, two or three c.c. being introduced. As the mass solidifies, it pushes the rectum inward and encroaches upon the lumen of the bowels. A new triangle is then made and the operation repeated until finally the entire prolapse is invaginated. This process is repeated until the anus is reached. A good-sized pad is placed across the anus and stitched directly to the buttox by a heavy silkworm-gut suture. This is removed in twenty-four hours. No after-treatment is required. The patient is kept in bed for four or five days and the bowels are allowed to act spontaneously. The age of the individuals varied from three to forty-eight years, and the size of the prolapse from 1½ to five inches in length. In each case, the bowel descended with every movement and remained down until it was replaced. Although several accidents have been reported by those who have done this work in this region, the author states that he has never had the slightest trouble. As a precaution against injecting it into a vein, he first uses a blunt needle; second, he takes particular pains to see that the point can be moved freely within the submucous tissue, and third, closes the large veins by raising a fold of the mucous membrane by artery forceps as described. The advantages of the method are (1) its rapidity; (2) its low mortality rate; (3) the absence of prolonged after treatment; (4) the mere fact that should it fail, the patient is probably no worse off than before it was attempted. Paget has demonstrated that paraffins melting at about 136° F. become incapsulated with fibrous tissue and remain unchanged. Morton has demonstrated that a paraffin melting at 109° F., if injected, will at the end of four months, be replaced by embryonic tissue. One of the author's cases, however, upon whom he had the opportunity to make an autopsy 4½ months after operation, showed that a simple encapsulation process only had gone on.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, OCTOBER 8, 1904.

"THE STREETS OF NEW YORK."

If cleanliness is next to godliness the streets of New York are in as solitary and unregenerate a state as even our lax municipal law allows. Why this should be at the present time it is hard to say, unless it is that this is the darkest hour which tradition teaches is apt to come before the dawn of a general election.

The white-winged street-cleaner, like the village tenor, is unquestionably doing the best that he can with his little perambulating go-cart, but this, with its patent reversible French-coffee-pot attachment, which holds a pint and boils over with every breath of air, has the unhappy habit of scattering its contents to the four winds of heaven, and "then the dust returning to the earth" makes such a mess that a cleanly crossing is impossible and every dragging-skirted woman is a rake at heart. Then, too, his coadjutor and side-partner, the pert and chirpy English sparrow, seems to be missing from his accustomed haunts. Either he has folded his wings and silently stolen away or he has been driven from his happy hunting grounds by the introduction of the all-conquering and starvation-producing automobile. At all events his self-sufficient little person is no longer seen hopping about in vast numbers on our thoroughfares, and his merry tit-willow note which, like that of the turtle, was loud in the land, seems now (as some of our imported Aldermen would express it) to have become the sound of the voice that is still.

That New York is not, and never can be, a second edition of "Spotless Town" goes without the saying, but its avenues need not so closely resemble that winter resort which is proverbially paved with good intentions, and certainly the admixture of some little drops of water with the prevailing little grains of sand would make it a much more beauteous land than the present Street Commissioners have apparently any idea of allowing it to become. Zion, we have been creditably informed, is paved with gold, but what the sub-strata of our streets really is cannot be told without the touchstone of the infrequent broom, though, judging from the occasional specimen bricks that have been exported to the confiding denizens of the rural districts, it must be something that does not even glitter. All this is, in itself, bad enough, but when the refuse of fruit stands, with an occasional dead and festering cat, is added to the unwashed tin cans that have been thrown from the equally unwashed tenement windows, the result is a "dump" that even a self-respecting goat would not deign to consider.

If this is a crime in the general streets, it is worse and becomes a blunder on the thoroughfares traversed by the electric trams.

Our lawgivers, when they prohibited expectoration on the cars, only succeeded, from a sanitary point of view, in robbing Peter to pay Paul, for the expectoration is now directed at the hard stone pavement, and as the outside seat is usually occupied by some specimen of the "end-seat-hog," who follows the biblical example and spits upon the ground, nothing has been gained. The streets are seldom washed or swept, save by rain or wind, and as the sputa cannot sink into the soil, it remains to be dried by the action of the sun, and is then blown into the faces of the passengers in an impalpable but most dangerous dust.

There was a time when the belated homegoers in the upper sections of the city found themselves surrounded in the wee small hours by groups of stalwart men whose clothes with horizontal stripes and close-cropped hair gave evidence that they were washing out their sins in expiation for the city's good. But now it seems that even the wicked have ceased from troubling and that the contractors' weary horses are at rest.

How long this period of the great unwashed will continue is a much more difficult question to answer than what will happen if some change does not take place. Given a little less rain and a trifle more intense heat, and the lower parts of the city will become unendurable. Discomfort in summer weather is hard to bear, but disease is worse, and in the crowded tenement districts the mortality among the young children, whose playground is in the gutter, will be enormous. We have all heard of the Ben-Butlerization of New Orleans in the bellum days, and there have been later rumors of what Wood accomplished in the cleaning up of Havana, but charity begins at home, and surely there is someone whose business it is, or who will make it his business, to grapple with this Augean task in our own slums.

The reasons lately assigned for this condition of the streets by one of the morning papers is hardly a valid excuse. It is true that the population of New York is now enormous and that the area occupied by the city is a vast one, but if this is divided into sections and each one thoroughly policed by men detailed for that purpose, it becomes simply a question of the multiplication of centers. As each of these subdivisions is cared for by its own set of cleaners, it is practically as easy to keep a thousand districts healthy and clean as it is one. When a section is overcrowded, and consequently in a more insanitary condition, the number of men employed can be increased, so that it is really, as are most matters of municipal reform, simply a question of dollars and cents.

As to the resident portion of the city, particularly in the upper parts, it is true that, as a rule, it is free from the refuse of garbage, the remains of dead animals, and the empty receptacles for canned foods. But even here the dirt and dust have accumulated into mounds which are scattered hither and yonder by every passing thunder-storm. It may be, however, as there is method in most forms of civic madness, that our City Fathers have allowed the dust to creep into little heaps as a protection to lovely woman with her necessarily uplifted skirts in these semi-autumn days of sudden gusts; even as the surprise-intending Legions of Rome were hidden by the blinding dust of their accompanying chariot wheels.

"The devil sent the whirling gust,
To blow the skirts awry;
But the good Lord sent the blinding dust,
To blow in the bad man's eye."

PIROPLASMOSIS.

Since each of the presidential candidates has finally agreed upon one point, namely that the Filipinos shall be given their independence "when they are qualified to have it," a long period of tropical colonization seems to be inevitably before us. That means the care of every variety of equatorial disease.

The rate at which the number of animal parasites, recognized as infesting the human body, has increased in the last few years, has been little short of astounding. Aside from the confessedly entertaining and graphic accounts of the subtleties of the "lazy bug," there is no parasite with more interesting characteristics than that which has recently been recognized and appropriately named Donovan's Piroplasm.

Coincident with Laveran and Mesnil, Donovan discovered this parasite in a patient in his wards at the General Hospital, Madras, India. In the *Lancet* of September 10, 1904, he gives a most interesting account of the history of his discoveries and cites numerous clinical observations which are of very great interest. During the last year he has had under observation no less than seventy-two patients, all suffering from this disease, a fact which shows how prevalent it must be throughout the tropics.

Of the identity of the piroplasma infection with the well-known tropical disease, Kala-azar, there can be no doubt. Edema of the feet occurs in about fifty per cent. of the cases. Bronchitis is about as frequently present. The skin almost always becomes covered with small ulcers which look very much like scabies, and it further resembles this disease, in that the itching is intense. Occasionally these skin lesions are not unlike Delhi boils. Pigmentation of the skin is very common. It may also occur in the eyes and mouth.

The most characteristic feature, however, of the clinical manifestations of the disease is revealed by physical examination. The spleen is almost always enormously enlarged, some of Donovan's patients having had this organ so hypertrophied as to weigh 80 ounces. This is a tremendous weight when one considers that some of the patients dying from this disease become so emaciated as to weigh, even though adults, only from 52 to 80 pounds.

The temperature is characterized by great irregularity, by being unaffected by quinine, arsenic, or any other drug, and by lasting from

two to six months. In the beginning it is decidedly intermittent, varying from 97° to 104° F. Occasionally the intermittance occurs with considerable regularity, morning and evening. The temperature occasionally sinks to 97° F. and remains there for a week or ten days, or even longer. Most noteworthy is it that the temperature is positively a determining factor in affecting the size of the spleen, the organ varying directly with it. During an exacerbation in many cases, the spleen has been observed to be far below the umbilicus, while within a week, should the temperature remain normal, the spleen will actually retract beneath the ribs. This diminution, however, in all cases is temporary.

It is of great interest to notice that although the liver is not so invariably affected in size, the maximum variations in temperature in about one-third of the cases produced an increase of liver dulness amounting to more than an inch beneath the costal margin.

Since the organism is very rarely found in the peripheral blood, and since even, if so found, it is always present in an entirely different shape from that assumed by the parasite when resident in the spleen, it is considered very necessary by Donovan to puncture the spleen in all suspicious cases. He very frankly records the death of one of his 110 cases of splenic puncture, post-mortem examination having shown it to be caused by a rapid intra-abdominal hemorrhage directly from the splenic wound. This fatality occurred in his twenty-second patient, and since then he has taken the precaution of administering large doses of calcium chloride and of keeping the patients quiet in bed for twenty-four hours after the operation.

This communication from the distinguished discoverer of the cause of Kala-azar is of profound interest to us even though, as suggested, we may not hold the Philippines indefinitely. The immediate and pressing interest in the matter would seem to be that Donovan in proving that the parasite is localized very strictly to the splenic circulation, has pointed out the only logical method of cure, viz., splenectomy. The pathological findings in this disease correspond, so far as the surgical indications go, very closely to those present in the cases of chronic malaria, which have been cured by this operation. The author himself does not advocate surgical treatment, but he very distinctly states that "quinine, arsenic, the salicylates, carbolic, creosote, iodine, etc., have all been used without producing the slightest effect."

It may not be premature to hope that Kala-azar, the etiology of which has been so cleverly demonstrated, will happily prove to be among those diseases which can be permanently cured by radical operation.

ECHOES AND NEWS.

NEW YORK.

Gift to Academy of Medicine.—By the will of the late Dr. Alfred W. Warden, of Weehawken, N. J., the sum of $1,000 is bequeathed to the New York Academy of Medicine.

Retirement of Dr. A. E. Macdonald.—Dr. A. E. Macdonald retired from the superintendency of the Manhattan State Hospital, East, on October 1, 1904, after which date and until further notice all communications relating to the hospital should be addressed to Dr. J. T. W. Rowe, Acting Superintendent. Dr. Macdonald's personal address will be Columbia Court, New York City.

New York Academy of Medicine.—Sections on Otology and on Pediatrics will meet next Thursday, October 13. In the Section on Otology Dr. W. H. Haskin will present a case of subdural abscess with necrosis of auditory canal. Dr. H. A. Alderton will read a paper on Some Points Respecting the Surgical Anatomy of the Facial Nerve. In the Pediatric Section, Dr. W. P. Spratling will read a paper on the Relation of Dentition to Epilepsy, and a discussion will be held on the Sequelæ of Cerebrospinal Meningitis. The following new members have been recommended for election to fellowship: John Cameron Anderson, Arthur A. Boyer, R. Bishop Canfield, Karl Connel, Colman Ward Cutler, Jeremiah Sweetser Ferguson, Herman C. Frauenthal, Lewis F. Frissell, James Morley Hitzrot, Burton J. Lee, Ralph Waldo Lobenstine, Frank Sherman Meara, Charles B. J. Mittelstaedt, Henry W. Mooney, Mortimer A. Moses, Samuel B. Olliphant, George Willis Robinson, Frederick J. Schoenenberger, Montgomery H. Sicard. For Associate fellowship: Frederick Stewart Baron, Henry R. Linville, George A. Soper, Edwin Henry Hall.

College of Physicians and Surgeons Reopens.—The formal opening of this institution for the coming academic year took place on Thursday afternoon, August 29. The chaplain of Columbia University read an appropriate selection from the Old Testament and followed it by a brief prayer. President Butler then arose and in a very fitting speech welcomed the students, both old and new, and congratulated them upon their larger responsibilities and greater possibilities for active and earnest endeavor. Speaking of the overcrowding in the medical profession, Dr. Butler cited France and Germany as concrete examples, but said that he felt sure this is not the case in the United States, at least not in the country districts, for there is many a town and hamlet without a medical representative, which is forced to send miles away in cases of urgent need.

Following this, the President introduced Professor John G. Curtis, Acting Dean of the Medical School, whose subject was: "Our Medical Teaching Considered in the Light of Ancient Error."

The ourden of Professor Curtis's essay was a historical review of medicine from the earliest times. He took up several of the old writers on medical subjects, translating at length from the writings of the Greeks and showing how keen was their conception of many things which we now acknowledge as facts. He emphasized the necessity of thorough courses in all subjects in which laboratory work can be given, and recommended his hearers to follow this method up as fully as possible after graduation. About 100 students are enrolled for the first year class, most of whom have received college diplomas in arts or science. Last year the entering class numbered 110, a falling off which is explained by the increased requirements for admission and by an additional tuition fee of fifty dollars. The graduating class has nearly 190 members, and is larger than that of last year.

Site for Skene Monument.—The Municipal Art Commission has approved of the designs for the $5,000 monument to be erected to the memory of the late Dr. Alexander J. C. Skene, the noted gynecologist of Brooklyn, at the north end of Prospect Park Circle, opposite the Soldiers and Sailors' Arch. The monument will be in the form of a white marble shaft thirteen feet high and six or eight feet wide, with a bronze bust of Dr. Skene.

Nassau County Hospital.—The net receipts of the fair given by Mrs. Clarence Mackay, at her home at Harbor Hill, on Saturday last, for the benefit of the Nassau County Hospital, were announced at the hospital to-day to be $10,750. An arrangement had previously been made between Mrs. Mackay and the hospital regarding the disposition of the proceeds of the fair. In accordance with this agreement Mrs. Mackay will give to the institution $2,000 a year for three years to assist in meeting the running expenses, and $4,150 will be set aside for the endowment fund. The balance, $600, will be used for improving the hospital grounds.

Typhoid in Albany.—There are a number of cases of typhoid fever in Albany, and the State Board of Health has issued an opinion on the cause. The Board ascribes the epidemic to the unsanitary conditions at summer hotels and boarding houses, and recommends a systematic investigation of such places for the purpose of obtaining reliable information to be kept on file at its office for general inspection, and also for the purpose of giving summer resort proprietors expert advice as to changes necessary to place their premises in safe conditions. The Board says: "This epidemic and many others investigated in the past have shown that hundreds of persons are every summer infected with typhoid fever at country resorts and return to the city before the disease manifests itself, thus making the number of cases reported to the city Boards of Health unusually large in the early fall. The same circumstances doubtless surround the increase of typhoid fever in cities in the spring, when many persons return from resorts in the South. It can hardly be expected that the proprietors of these resorts will be men of knowledge and skill in sanitary matters. Doubtless ninety-five per cent of all resorts are established without giving the plans of the sanitary arrangements any proper expert consideration. The majority of owners of such places would be more than willing to correct any existing defects if they could be told by a proper authority, not interested in obtaining contracts, just what was needed. The protection of the public making their accustomed use of these resorts requires that their representatives in the State government provide for the badly needed extension of the public health service to the inspection and supervision of the sanitary arrangements of public resorts. The cost of such a service would not be greater than the loss to the people through even one of the epidemics of typhoid fever at present quite frequntly occurring in various parts of the State."

PHILADELPHIA.

University of Pennsylvania.—At the opening of the University on September 30, the students of the Medical Department presented Provost Harrison with a silver loving cup. The inscription states that the gift is in appreciation of earnest efforts in behalf of the medical department. A gift of $100,000 to the Veterinary Department was announced, the donor withholding his name. In pursuance of efforts to stop hazing, each member of the Sophomore class of the college received a letter from the Dean stating that participation in hazing will be punished.

Jefferson Medical College.—Because of the large increase in the faculty of this institution, the following disposition has been made of the studies in the Senior year: Four major branches are recognized—Therapeutics, Obstetrics, Surgery, and Practice of Medicine. The remainder are placed in three groups: (a) Gynecology, Neurology, and Genito-urinary Surgery; (b) Orthopedic Surgery, Dermatology, and Pediatrics; (c) Ophthalmology, Laryngology, and Otology. Each of these groups has the value of one major branch. Examination in group a will be in the spring, with the majors, in groups b and c during the first week in March.

Coroner System Defended.—During the recent meeting at Scranton, of the State Convention of County Commissioners, the question of the abolition of the office of Coroner in Pennsylvania was seriously debated. In regard to the matter, Coroner Dugan, of Philadelphia, says he is sure the office is a permanent fixture in this State. "It would require an amendment to the constitution to abolish the office and, considering the great assistance it is to the District Attorney, he doubts very much if its abolition will ever be effected. Within the past six months the work of this office has resulted in the breaking up of the notorious malpractice syndicate and driving from the city of persons engaged in inhuman infant traffic. Several mysterious murders have also been completely brought to light, all of which goes to prove what an important adjunct it is to municipal government. The office of coroner is an ancient and important institution. Its name may be changed, but its duties and obligations will ever remain the same."

State Board and New York Examinations.—The Medical Council of Pennsylvania, at the June meeting, adopted the following resolution: "*Resolved*, that each examining board be authorized to accept, if they see proper, the grades of graduates in medicine obtained in examinations before the State Board of New York on the branches of the first two years of the medical course; that candidates submit their grades to their respective examiners who shall pass judgment upon the same; and that they shall be required to deposit the usual examination fee of $25 with the understanding that they get a rebate of $10 in case their grades from New York are accepted, and that this rule remain in force for the Pennsyl-

vania examiners until the close of the December examination in 1905."

Chestnut Hill Hospital Opened.—Many residents of Chestnut Hill and Mount Airy attended the opening of the new hospital at the former place October 3. The institution comprises two three-story buildings used formerly as dwellings. Miss Rena J. Ward is to act as superintendent.

CHICAGO.

Opening Exercises.—The opening exercises of the Chicago College of Physicians and Surgeons (Medical Department of the University of Illinois) were held September 27. Dr. C. C. O'Byrne delivered an address on behalf of the Faculty.

Commencement Exercises of Illinois Medical College.—The exercises of this college were held September 29 at Handel Hall. The principal address was delivered by Judge Holdom. Degrees were conferred upon forty-seven doctors and druggists by Dr. H. H. Brown, ex-President of the College. A banquet was held in the evening at the Auditorium Hotel. Dr. S. S. Bishop acted as toastmaster, and after-dinner speeches were made by Judge John Barton Payne, Judge Holdom, Prof. C. W. French, of the Hyde Park High School, Rev. J. L. Jackson, and Drs. H. H. Brown, Wm. Rittenhouse, and B. B. Eads.

American College of Medicine and Surgery.—The opening exercises of this college were recently held. Addresses were delivered by Prof. Gammage and Dr. Truman W. Brophy. Fifty-one freshmen matriculated. The college has about 250 students. This is the fourth annual opening.

Donations for Institutions.—The will of Mrs. Elizabeth Green Kelley leaves half of a $600,000 estate to charitable and educational institutions. To the University of Chicago, it is said, $100,000 was given. The Home for Incurables and the Chicago Orphan Asylum are to receive $60,000 each, the Presbyterian Hospital $25,000, and the Public Library $30,000. St. Luke's Hospital is also remembered.

Dr. Northrup in Chicago.—Dr. W. P. Northrup, of New York, addressed the Chicago Medical Society and the Pediatric Society, in joint session, Wednesday evening, September 28. Subject: "Pneumonia in infant's early diagnosis and treatment apart from drugs."

CANADA.

Personals.—Dr. J. V. Anglin, assistant superintendent at the Protestant Hospital for the Insane, at Verdun, Quebec, has been appointed medical superintendent of the Provincial Hospital for Nervous Diseases at St. John, N. B. Dr. Anglin is a graduate of Queen's University, and has devoted all his professional life to the care of those afflicted with insanity and allied diseases.

Dr. Squire Sprigge, editor of the *Lancet*, is visiting Mr. Justice Moss, of Toronto.

Dr. S. J. Tunstall, Vancouver, B. C., President of the Canadian Medical Association, has been visiting in Montreal, Toronto, Boston and New York. At the latter place he saw Mr. Mayo Robson and Dr. MacGillivray, of Edinburgh, embark for England.

The following Toronto practitioners have been placed in nomination for representatives on the Senate of Toronto University from the Medical Faculty: Dr. J. A. Temple, Mr. I. H. Cameron, Dr. Geo. A. Bingham, Dr. Adam H. Wright and Dr. W. H. B. Aikins.

Mr. Irving H. Cameron, Professor J. J. McKenzie and Dr. G. H. Burnham have returned to Toronto from England. They formed a deputation which waited on the Council of the British Medical Association to invite that body to convene in Toronto in 1906. The Council recommended that the invitation be accepted, so Toronto is preparing to have the British Medical Association in that year.

Dr. R. W. Bruce Smith, of Brockville, Ont., assistant physician at the asylum for the insane there, has been appointed Inspector of Prisons and Public Charities in Ontario, in succession to Dr. T. F. Chamberlain, who has resigned owing to ill health. Dr. Smith will be succeeded by Dr. J. C. Mitchell, of the Toronto Asylum, who in turn will have his place filled by the present relieving officer, Dr. Harris.

Dr. J. A. Leduc, who has been house physician at the Notre Dame Hospital, Montreal, has left for Boston, where he will spend a year in the Civic Hospital of that city. On his return to Montreal he will take up work in connection with the proposed new contagious diseases hospital to be erected in connection with the Notre Dame institution.

Dr. J. B. McConnell, Montreal, vice-dean of the Medical Faculty of Bishop's College University, has been elected second vice-president of the College of Physicians and Surgeons of the Province of Quebec.

Dr. Thompson, a member of the British House of Commons, at present on a visit to America to inspect the medical institutions on this side of the Atlantic, has been visiting the hospitals and medical colleges of Montreal during the past week, and expresses himself as being delighted and pleased with the perfect system of regularity in operation in those institutions.

Sir Felix Semon, one of the distinguished throat specialists of England, is on a visit to Montreal and is the guest of Dr. H. S. Birkett, of that city. Sir Felix enjoys a reputation as a clever stalker of deer in Scotland, and has gone on a moose hunting expedition into the heart of New Brunswick.

Quebec College of Physicians and Surgeons.—The elections for the College of Physicians and Surgeons of Quebec were held at Laval University in the City of Quebec, on September 28, a very large attendance of medical men being present from different parts of the province. Dr. E. P. Lachapelle, of Montreal, was re-elected president; Dr. D. Brochu, of Quebec, was elected first vice-president, and Dr. J. B. McConnell, of Montreal, was elected second vice-president. Dr. A. R. Marsolais, of Montreal, was elected registrar, with Dr. A. Jobin, of Quebec, treasurer, and Dr. P. O. Faucher, of Quebec, as secretary.

Magnificent Gift to Toronto General Hospital.—The Board of Trustees of the Toronto General Hospital have decided to accept the most generous offer of Mr. Cawthra Mulock, of Toronto, to build, equip and furnish at an expense of $100,000 a separate building or wing for the purpose of the outpatient department of this institution. There is, as the wealthy donor states in his leter to the chairman of the Board, the most urgent need at the present time for a properly equipped outpatient department in conection with this hospital, which will at the same time provide free service for Toronto's poor, and also provide satisfactory clinical teaching for the six or seven hundred medical students at the University of Toronto. It has not as yet been decided whether the new building should be erected alongside of the present hospital building or located near the new

medical building of the University. The latter would probably be preferable, as it would be convenient for patients, while at the same time it would offer better advantages to the medical students.

Trinity Confers Her Last Degrees.—The last convocation of Trinity University for conferring medical, arts and other degrees was held during the past week. The Chancellor of the University, Mr. Christopher Robinson, K. C., presided, and expressed regret that a function which had been carried on for the past fifty years would now cease, owing to federation with the University of Toronto.

Ontario's Health for the Month of August.—The total deaths from all causes in Ontario during the month of August numbered 2,024, which gives a death rate per 1,000 of 12.4 per cent. Regarding infectious diseases the cases and deaths show an increase of 43.1 per cent. for the former and an increase of 20.5 per cent. for the latter over the corresponding months of last year, which increase is due largely to typhoid and diphtheria. There was plenty of typhoid fever throughout the province during the month, but those places particularly affected were London, St. Thomas and North Bay. There were eight cases of smallpox with no deaths, 132 cases of scarlet fever with nine deaths, 172 of diphtheria with 25 deaths, three of measles with one death, 19 of whooping cough with 15 deaths, 293 cases of typhoid with 50 deaths and 196 cases of tuberculosis with 188 deaths.

GENERAL.

Boston Bequests.—Public bequests aggregating over $1,000,000, the largest being a gift of $250,000 to the city of New Bedford, are contained in the will of Mrs. Sarah Potter, of Boston, which was filed for probate yesterday afternoon.. To the Boston Medical Library is bequeathed $150,000; to the Kindergarten for the Blind, at Jamaica Plain, $100,000 and $50,000 to each of the following: Harvard University, Boston Home for Incurables, Hospital Cottages for Children, at Baldwinsville, Mass.; Free Hospital for Women at Brookline, and the Massachusetts College of Pharmacy.

Japanese Sanitary Work Praised.—Among the passengers arriving on the steamship Mongolia, at San Francisco, from the Orient, was Dr. Louis L. Seaman, who has served as a surgeon in the United States Army, and who has been studying Japanese methods of surgery in the campaign of that army against the Russians. In his opinion, Japan is far ahead of all other nations of the world in the organization of her sanitary branch of the army, and has been the first to anticipate and take adequate measures against disease, recognizing the fact that the greater number of deaths in war are caused, not by bullets, but by sickness.

Genius and Eccentricity.—The following story recently told by Mrs. Tweedie concerning Ibsen and his methods will be enjoyed by those who hunt for eccentricities in people of genius. Speaking of a recent visit made by her to Ibsen's home, she says: "On the table beside the inkstand was a small tray. Its contents were extraordinary—some little wooden carved Swiss bears, a diminutive black devil, small cats, dogs, and rabbits made of copper, one of which was playing a violin.

"'What are those funny little things?' I ventured to ask.

"'I never write a single line of any of my dramas unles that tray and its occupants are before me on the table. I could not write without them. It may seem strange—perhaps it is—but I cannot write without them,' he repeated. 'Why I use them is my own secret,' and he laughed quietly."

English Lunacy Reports.—The last annual report of the English lunacy commissioners is a portentous document, filling 500 pages of a blue book recently issued. It makes rather laborious reading, but contains some interesting and disquieting facts. Among them are the following: On January 1, 1904, there were 117,199 persons certified as insane in England and Wales, or 3,235 in excess of the number reported on January 1, 1903. In the ten years ending December 31, 1903, the average annual increase in the number of insane was 2,513 and the increase in 1903 exceeded that average by 821. On January 1, 1904, the total number of officially reported insane to the estimated population of England and Wales was in the proportion of 1 to 288; or, in other words, the ratio of the insane per 10,000 of population was 34.71 while last year on the same day the ratio was 34.14. The commissioners point out that in dealing with the gross figures alone there has been a rise in the total numbers from 113,964 to 117,199, *i.e.*, an increase of 2.8 per cent., but the increase of the one ratio over the other was 1.7 per cent., a rate which represents more accurately the actual growth of insanity, since it takes into account the growth in population. The total increase in this ratio for the past ten years was 13.1 per cent., whereas the increase in the numbers of the insane during the same period was 27.3 per cent. In 1894 the proportion of insane to total population was as 1 to 327; in 1904 it is as 1 to 288, and while the insane have increased from 92,000 to 117,000 the general population has grown from about 30,000,000 to 33,750,000. Alcoholic intemperance figures prominently among the physical causes for insanity.

Are We Really Civilized.—"About 2250 B.C.," writes Dr. P. M. Jones, in a recent editorial anent the progressiveness of American civilization, "Hammurabi, King of Babylonia, established certain laws which he embodied in a code, inscribed upon stone stelæ, and set up in the principal cities of his domain. We are rather inclined to look upon medical legislation as somewhat modern; that is because we do not know any better. In Hammurabi's time, medicine was specialized; surgery was a distinct branch of the science; quacks and pretenders were known and legislated against. From advance sheets of a translation of these laws by Professor Harper, President of the University of Chicago, we read: "If a physician operates on a man (*please note that the physician did not 'operate a case' in Hammurabi's time!*) for a severe wound with a bronze lancet and saves the man's life, or, if he opens an abscess (in the eye) of a man with a bronze lancet, and saves that man's eye, he shall receive ten shekels of silver (as his fee)." But, under the same circumstances, if he causes the man's death, or destroys the man's eye, "they shall cut off his fingers." That would tend to discourage unskilled operators and experimental operations. In 1508 the Royal College of Surgeons was authorized by charter to examine those who would practise medicine and physic, and to issue license to those who were found qualified. This would not have been done had it not been found necessary, nor would Hammurabi, 4154 years ago, have had need to discourage quacks, had they not existed. Yet, in this year of grace, 1904, there come those who practise medicine and physic, and they

stand before the highest court in the State, in the persons of their attorneys, and say they prefer to have no law governing the practise of medicine. This is indeed a progressive age, when educated men will strive to put the commonwealth back of the time of Babylonia; to make us lose what has been gained in 4,154 years!

Cost of Tuberculosis.—In a recent paper on the cost of tuberculosis to the State of Illinois (*Illinois Medical Journal*, September, 1904), Dr. H. M. Thomas says that consumption costs the State an annual loss of thousands of lives. Many of these lives can be saved if placed in hospitals or sanitoria. In view of the excessive mortality from this disease and in order that this may be markedly diminished, it is a decided economic advantage for the State to maintain hospitals for its consumptive poor. Some sanatoria claim 70 per cent. of cases cured when the patients are admitted to treatment in the earlier stages. This estimate is probably correct. Incipient tuberculosis is one of the diseases most easily cured. It is fair to estimate that under proper treatment in sanatoria 50 to 75 per cent. of the consumptive patients in the earlier stages would be cured. With 7,026 deaths from tuberculosis in Illinois for the year 1903, if we can save through the maintenance of sanatoria by the State 50 per cent. instead of 7,026 deaths there would be but 3,513 deaths. Estimating the annual economic loss to the State from tuberculosis at $36,000,000, or at the rate of at least $100,000 a day, sanatoria would save to the State annually at least $18,000,000. Is it not therefore wise for the State through the erection of sanatoria to annually effect a saving of this vast sum? Viewed strictly from a standpoint of the annual economic loss, and considered wholly from its financial aspect, and laying aside all huumanitarian and philanthropic considerations, our State is justified in proceeding to assume the care of its consumptive poor. It is not to be expected that sanatoria will abolish consumption. The spread of contagious diseases through quarantine is not wholly prevented, and yet we continue to quarantine. The establishment of sanatoria would not only be of great economic value to the State, but would, through their sanitary environments as well as educational benefit, be of great and lasting value to our State. Illinois, the State of vast industrial activity, tremendous agricultural resources and comprehensive educational institutions; the home of great statesmen, scientists and philanthropists, must be freed from the blight and devastation of tuberculosis. Science has clearly pointed the way for the accomplishment of this end. Let us not be blind to or negligent of our duty. Let us each and all do our share that in the end tuberculosis may forever be banished from our midst.

OBITUARY.

Dr. David D. Wickham, the oldest practising physician in Orange county, N. Y., died at his home in Port Jervis, Saturday night, of acute gastritis, at the age of seventy-four years. He was born in Wantage township, Sussex county. After practising medicine fifteen years in Sussex county he went to Port Jervis in 1872 and accumulated a large fortune in practise. He gave the colored people of Port Jervis a handsome church building and to Drew Methodist Church of that place $5,000, this sum being the amount of a mortgage held by him, to be canceled on the death of his wife.

Dr. Merric Bemis, for fifteen years prior to 1872 Superintendent of the Worcester (Mass.) Lunatic Hospital, and widely known as an expert on insanity, died suddenly last Monday, of Bright's disease, aged eighty-four years. Of late years Dr. Bemis, assisted by his son, Dr. John M. Bemis, had managed a large private asylum for the insane.

Dr. Phineas J. Horwitz, of 1919 Walnut Street, Philadelphia, died at Bar Harbor, Me., September 28, after a long illness. Dr. Horwitz was in charge of the Tampico Hospital during the Mexican War, and later was medical inspector and director in the United States navy. He also had charge of tabulating the casualties of the Civil War. Dr. Horwitz was eighty-two years old. He was the father of Dr. Orville Horwitz, of Philadelphia.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, September 24.

THE CHAIR OF MEDICINE AT OXFORD—THE BRITISH MEDICAL ASSOCIATION AND THE PROTECTION OF PRACTICIONERS—DEATHS IN THE MEDICAL PROFESSION—VACCINATION IN ENGLAND.

Holiday-making and other things have interrupted the continuity of this correspondence so long that the meeting of the British Medical Association at Oxford is now ancient history. This is the less to be regretted, however, since the most interesting part of the scientific proceedings has already been published in the Medical News, and there is little else to record of the gathering beyond the fact that it was in the conventional sense "successful." The most important event connected with it was the engineering which ended in the capture of the Regius Professorship of Medicine by the anti-Sanderson faction. The state of affairs was described in your columns some months ago. Sir John Burdon Sanderson, the previous occupant of the chair, was anxious that it should be transformed into a chair of pure pathology, and strongly urged the appointment of Dr. James Ritchie, who is the University lecturer on that branch of medical science. Ritchie, however, has the disadvantage in the eyes of Oxford men of the high and mighty type—a breed of superior person peculiar to this happy island—of being only an adopted son of their august Alma Mater; moreover, his speech betrayeth him perhaps too readily as a native of Caledonia stern and wild. Against these deficiencies it matters nothing to your academic prig that he is one of the first pathologists in the United Kingdom and a man of large culture and breadth of mind. Therefore, although the teaching staff supported Ritchie he has been set aside. Till shortly before the announcement of the election of Professor William Osler it seemed likely that Ritchie would get the appointment as his opponents had no candidate of real eminence whom they could put forward for the office. The suggestion of Osler must have been a veritable godsend to them and plans were at once laid to secure him. It had been arranged that he should stay with the Dean of Christ Church, but at the last moment Burdon Sanderson carried him off to his lair. Sanderson has, rightly or wrongly, the reputation of an arch-Jesuit, and it was greatly feared that he might cajole or bore Osler out of accepting the post. Nevertheless, Osler was hooked and safely landed, and by way of compensation Ritchie's lectureship is, I believe, to be raised to the dignity of a chair, to which an increased stipend

will be attached. This question of stipend, it may be mentioned, was one of the difficulties in the way of getting a clinician of any professional position to accept the chair. From this point of view the University has certainly been fortunate in securing Osler, but it may be doubted whether that distinguished physician has made an equally good bargain for himself. The Chair of Medicine at Oxford is an expensive luxury. It is an open secret that the Regius Professor at Cambridge spends a good deal more than he receives on maintaining the dignity of his position, entertaining distinguished visitors and the like. Moreover, his time is so fully occupied with multifarious academic duties that he has no time for private practice. Dr. Clifford Allbutt is, for a physician, a wealthy man, having for many years had the lion's share of consulting practice in the North of England, and he was thus enabled to accumulate a fortune which makes him altogether independent of his profession. I do not know if Dr. Osler is so fortunately situated, but it is to be presumed that he counted the cost of the dignity offered to him and accepted it with his eyes open.

The British Medical Association was reorganized two or three years ago, with results which the promoters of the "reform" profess to regard highly satisfactory. The average man would, however, probably say of the change as Falstaff said of Shallow, whom he remembered at Clement's Inn, that its dimensions are to any thick sight invisible. The true inwardness of the transformation may be expressed in the statement that, whereas the Association used to be managed by clique, now it is governed by caucus. The truth is, the Association has for some years past been becoming more and more a one-man show of which Victor Horsley has been the boss. It is said by the reformers that under the old constitution the management of the Association was too autocratic, but it is clear that the rule of a representative Council elected by the Branches could never in the very nature of things have been so autocratic as a despot. The members of the medical profession in this country are sheeplike in their obedience to any one who will take the trouble to lead them, but signs are not wanting that members are beginning to be a little weary of the "boss" system. It is pretty plain too that the boss himself, who is eminently cute, sees possibilities of revolt; the cloud is far off indeed and no bigger than a man's hand, but it is there. Like a prudent navigator, therefore, he is taking in sail and preparing to run. Already one or two of his thanes seem to be inclined to fly from him, and although he has still a compact body of devoted henchmen at his back, his influence has unquestionably waned to some extent within the last twelve months. In proof of this may be cited the significant fact that at the recent annual meeting a scheme for the creation of a department of medical defence (protection against vexatious lawsuits, blackmail, etc.) in the Association, of which he was an initiator and a most strenuous promoter, failed to secure adoption, and was referred back to the Committee which had framed it under his inspiration and guidance. The question is therefore shelved for the present, but it is tolerably safe to predict that the British Medical Association will at some time or another be compelled to undertake the defense of its members against dissatisfied patients and speculative attorneys. There are, however, many difficulties in the way. One of these is the apathy of a large proportion of the profession and the unwillingness of others to pay for a luxury which they think should be provided for them without extra charge. But the chief obstacle is the existence of several independent societies which have for years been successfully discharging the protective function which the British Medical Association is urged to undertake. These societies—of which the Medical Defense Union, having a membership of six thousand or thereabouts, is the chief—not unwarrantably think they have justified their existence and are by no means eager to accept an invitation to allow themselves to be absorbed by the British Medical Association. For this attitude they are seriously taken to task by the satellites of the "boss." The situation reminds one of the famous sketch of an episode in the French Revolution where a cook is shown in the farmyard asking the animals with what sauce they would like to be cooked. To their objection that they do not wish to be cooked, the reply is: *Vous vous écartez de la question!*

Some notable figures in the British profession have recently disappeared. Sir William Mitchell Banks, who largely contributed to raise the Liverpool School of Medicine from the position of a small struggling local institution to that of a University faculty, was a surgeon who combined the dash of the older operators with the scientific precision of the moderns. He was the pioneer in this country of the thoroughgoing operations for cancer of the breast which are now blessed by many who at first cursed them. He was a lover of books, but was disposed to act on Charles Lamb's counsel: "When a new book comes out, read an old one." He was a breezy speaker and a racy writer, qualities which made him very successful as a teacher. He took a leading place in Liverpool Society where he was noted for his good stories and his ready repartees. In appearance and character he was, though a born Scot, a typical John Bull. Sir Frederic Bateman was a physician of Norwich, an ancient city made famous by another knightly physician, Sir Thomas Browne. He was the author of the first treatise on aphasia published in this country, and it was for his investigations on this subject that his knighthood was conferred upon him. Dr. R. E. Dudgeon—though not in a medical sense of the household of the faith, for he was a disciple of Hahnemann—was a remarkable man in his way. He translated the works of his master into English and was the inventor of a sphygmograph which used to be found in the pockets of many physicians who were too sensible to ask if any good came out of Nazareth. Among his patients were notabilities such as John Bright, James Russell Lowell, and Samuel Butler, the author of the philosophical romance "Erewhon." It was owing to Dudgeon's influence that a clause was inserted in the Medical Act making it illegal for medical authorities to withhold, on the sole ground of medical opinions, degrees from candidates who had passed their examinations. It is said that during the fatal illness of the late Queen Victoria's husband, Dudgeon received a royal command to hold himself in readiness to proceed to Windsor at a moment's notice. The summons never came however, and the Prince Consort died in the arms—medically speaking—of William Jenner, who administered the last consolations of orthodox medicine.

The report of the Medical Officer to the Local Government Board, just issued, shows that the Vaccination Act has been better observed in the last two or three years than was formerly the case. In 1901 only 13 per cent. of the 929,882 infants born were not accounted for by the vaccination officers; the corresponding percentage in the three years preceding was 21.5 for 1898, 17.2 for 1899, and 15.6 for 1900. If allowance is made for the exemption of the children of "conscientious objectors," who numbered 30,925 in 1901, the percentage of infants unvaccinated in that year was

17.3. This compares favorably with 19.9 per cent. in 1900, 20.8 per cent. in 1899, and 26.6 per cent. in 1898, figures which again show a steady growth of the practice of vaccination. The detailed tables show that 70.8 per cent. of the children born in England in 1901 were successfully vaccinated—an increase of 2.8 per cent. as compared with the previous year; and that the percentage of "conscientious objectors'" children remained the same, namely, 4.5. In Wales, where vaccination is more popular, 82 per cent. of the children born were successfully vaccinated, and only 0.6 per cent. of the total number were exempted for a "conscientious objection." In London, as a whole, 64.3 per cent. of the children born in 1901 were vaccinated, showing an increase of 2.6 per cent. over the previous year, while the "conscientious objectors" increased from 1 to 1.1 per cent. of the total.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Regular Monthly Meeting, held Monday, May 23, 1904.

The President, Wendell C. Phillips, M.D., in the Chair.

The Passing of Neurasthenia.—Dr. Charles L. Dana opened the scientific business of the evening with the reading of a paper bearing this title.

Neurasthenia Covers a Multitude of Diseases.—Dr. Dana said that he was associated with Dr. Beard when he introduced the word neurasthenia, and at that time he considered it, as he does now, a useful word. Unfortunately, however, a number of affections have come to be included under it which might well merit a more definite designation given them in the course of the development of diagnosis. Neurasthenia replaces a series of even more indefinite terms, as dyspepsia, latent gout, hypochondria, hysteria, the spleen, the vapors, liver troubles, or the apparently more scientific yet scarcely less definite designations, lithemia, oxaluria and even vaguer terms. The word neurasthenia, itself, however, has come to impede progress somewhat by making practitioners satisfied with hasty diagnosis.

Melancholia and Neurasthenia.—Dr. Dana's attention was first called to the too wide application of the word neurasthenia by having patients who were evidently suffering from melancholia tell him so frequently that they had suffered some time before from neurasthenia or nervous prostration. Careful investigation of these cases seemed to make it clear that many of the hypochondriacal states of middle and later life which are really of melancholy nature are made to appear less serious to patients by the comforting term neurasthenia. Of a series of one hundred cases of melancholia, one-third of them had suffered from previous attacks, which had been diagnosed as nervous exhaustion. In all of these apathy, retardation, difficulty and slowness of thought, were present. The real ailment was evidently recurrent melancholia. The difficulty in the diagnosis was the differentiation between the psychosis and the neurosis.

The Phobias.—Dr. Beard laid considerable stress in many cases of neurasthenia on the presence of unreasoning fears. For these he invented many of the names by which they have since become familiar. Misophobia, siderophobia, acrophobia and the like. In the severer forms these patients are really insane. The basis of their condition is evidently a psychosis and not a neurosis. It might be spoken of as a neurasthenic insanity. There is a term, however, for this which is coming into more common use, phrenasthenia or psychasthenia. General practitioners are familiar with one form of this so-called sexual hypochondria in which patients get a fixed idea that their sexual powers are seriously impaired, or that they are suffering from loss of manhood. In women there are hysterical conditions, evidently of mental or nervous origin. Many of these might be spoken of as abortive types of exhaustion psychoses.

Neurasthenia in the Young.—When young persons become queer and lose interest in their work and fail to have the ordinary interests that young persons of their state in life enjoy, it is the custom sometimes to speak of their condition as neurasthenia. Such persons may run away from home, or run away from school, or insist on staying home from school, claiming that they are unable to work. Needless to say in these cases the difficulty is mental and not neurotic. Of late years the insanities of adolescence have come to be studied more than formerly, and the serious condition known as dementia præcox (precocious dementia), may be preceded by pseudo-neurasthenic symptoms. Paranoics often suffer from symptoms that are not manifestly psychical and yet are due to their congenital mental condition. Depression is not uncommon and often is the keynote by which these cases are recognized from true neurasthenia.

Physical Conditions.—A certain number of physical conditions that are very different from neurasthenia may be confounded with it when the symtoms are incipient and obscure. In young people the status lymphaticus with the phlegmatic condition sometimes consequent upon it, may prove difficult of recognition. In older people, arteriosclerosis may give rise to the tired feelings, the sluggish mental operations, the readiness of fatigue and the general discouragement which is sometimes considered to be one of the most prominent symptoms of neurasthenia. During the next ten years, as the result of more careful diagnosis, the use of the word neurasthenia will probably disappear completely, or certainly to a very great extent, from serious diagnosis.

Phobias Pathognomonic of Neurasthenia.—Dr. Rockwell, in discussing Dr. Dana's paper, said that while many groups of nervous symptoms with psychic manifestations had been grouped under the word neurasthenia, in Dr. Beard's mind there seemed to be one ailment that was pathognomonic of the disease. This was some form of phobia or morbid fear. When patients suffer from this and are unable to control it, there is often found a physical basis in a tremor evidently originating in the nervous system and the symptoms are corporeal rather than mental. For this group of cases the word neurasthenia should still be preserved.

Dr. Robert T. Morris said that surgeons see many cases of neurasthenia and Dr. Dana's explanation that they are psychoses rather than neuroses is helpful. Another interesting feature is the declaration that migratory fever, what the Germans call Wanderlust, which sometimes makes young folks run away from home and which seems to be a sort of reversion to the migratory instinct that occurs so commonly in birds and in a few animals, is of psychic origin.

Some Conceal Crack Better.—Dr. Martin pleaded for the use of the word neurasthenia for charity's sake. There are many patients and their friends who

are satisfied with the diagnosis neurasthenia, when perhaps the true condition is a slight mental aberration. So many persons, however, suffer from slight mental aberrations that it would be too bad to label them all. As it has been said, "Nearly all the world is cracked, but some succeed in concealing the crack better than others." The use of the word psychosis will inevitably lead to the suspicion of insanity and to unfortunate consequences, especially to the arousing of prejudices.

Dr. Dana, in closing the discussion, said that major psychoses must be confined in asylums; minor psychoses, however, can well be treated quite apart from the prejudices as to insanity and quite successfully.

The Curette in Acne.—Dr. George Henry Fox said that it has taken him thirty years to learn the use of the curette as the best local treatment for acne. It is far better than any ointment or lotion devised for the purpose. Not that local treatment is of no value, but it is of comparatively little value, so that since he has become accustomed to the use of the curette, Dr. Fox rarely thinks of prescribing mercury or sulphur or any of the other favorite local remedies. The use of the curette is not new and is not original with Dr. Fox, but he considers that its more general use would be extremely advisable.

Technic and Instrument.—The instrument employed by Dr. Fox is an ordinary dull ring curette, such as the gynecologists frequently employ. Where the acne is in an acute stage, its use will give rise to a number of bleeding points and will prove a source of considerable discomfort to the patient, besides not improving his appearance for several days. After a very few days, however, the improvement is so marked, that the patient is very willing to have the treatment repeated as often as seems to be necessary. After the use of the curette, some mild lotion such as borolyptol can be used. Patients should be taught to scrub their faces with a coarse towel and to use cold instead of hot water in washing. Hot water is often recommended in conditions of acne, but it relaxes the skin, while cold water acts as a tonic.

General Treatment.—Acne patients need general treatment even more than local applications. The diet should be carefully restricted and outdoor exercise should be strongly recommended. The doctor must be sure that the patient spends considerable time in the outdoor air. Systematic disturbances of any kind, as any of the forms of dyspepsia, constipation, or genito-urinary conditions, or pelvic troubles in women, must be corrected, of course, or the local treatment will bring about improvement in vain and relapses will inevitably occur.

Dr. Phillips said that he has seen the result of the curettage of acne cases and has been surprised at the rapid improvement which results. The treatment is rough and harsh, causes a good deal of pain, especially to sensitive women, but it does so much good that they are perfectly willing to stand the discomfort. Human pride is always enough to support one in bearing a pain where there is to be an improvement in appearance.

Water Anesthesia.—Dr. Samuel Gant reported a series of operations on the rectum including fistulæ, piles, prolapse, stricture of the rectum, treated under local anesthesia produced by the introduction of water into the tissues. He was led to the observation that water was sufficient to produce anesthesia by trials with weak solutions of cocaine and eucaine. He found that if the solution was not retained in the tissues no anesthetic effect was produced, no matter how strong the solution. On the other hand, satisfactory local anesthesia was obtained, no matter how diluted the solution was, provided it was held in the tissues. He found also that the weaker the solution the less likelihood was there no bleeding afterward, and so he began to use plain water or normal saline solution.

Disadvantages of Cocaine.—The most serious drawback with regard to cocaine or eucaine solution in local anesthesia consists in the fact that there is apt to be considerable hemorrhage after their use. This seems to be due to a paralysis of the blood vessel walls because of the presence of the blood not permitting them to retract normally after the operation is concluded. This does not happen with water anesthesia. The anesthetic effect is produced quite as quickly, and within thirty seconds complete anesthesia for the skin incision can be obtained. After operations done with cocaine one out of every three or four patients will have to be taken care of for several hours until the effect of the drug wears off. Immediately after an operation done with water-anesthesia, the patient may be permitted to leave the office and go about his usual occupation. Dr. Gant has now done some 250 operations by this method. It may be used of course for other parts of the body besides the rectum, with quite as good success.

Technic of Method.—Patients must be frankly told that the first injection causes pain, or they will lose confidence in the physician. The first effect is a stinging pain. This is followed by the appearance of a welt and then the anesthetic effect has begun. Any part of this welt can then be used for further injection without causing pain. It is important that the water should be retained in the injected area and at times, if the fatty layer of the skin is loose and allows the water to flow off, no anesthesia results. The anesthetic effect seems to be due to the pressure upon peripheral nerve endings of the water present. This prevents them from carrying sensory impulses.

Further Advantages of the Method.—In all operations performed by this method, the patients may be allowed at once to leave the office or the hospital, and they need but very little after-treatment. Dr. Gant prefers to have his patients return so as to dress them himself, rather than to commit them to an assistant. The results are always more satisfactory. There is no necessity for locking up the bowels. This only disturbs the patient and often proves a source of discomfort. On the other hand, there is no necessity for making the stools absolutely liquid, for a diarrheic condition induces tenesmus and produces a spasmodic feeling that adds to the discomfort of the patient, without doing any special good. The diet is not very much restricted, but the patient is asked to take a regular diet with an abundance of liquid and just sufficient salts to make the stools soft and remove all sources of irritation for the operated rectum and anus.

Dr. Elmer Lee, in discussing Dr. Gant's paper, said that this method of obtaining local anesthesia can be used with good effect for the removal of sebaceous tumors, or for other superficial operations where the injections can be made without difficulty. There seems to be no doubt that the anesthesia is due to paralysis of the superficial sensory nerves. The effect corresponds to that obtained when the arm is held up for some minutes, until the blood has flowed out of it, and then surrounded by a rubber tube or an Esmarch bandage. Under these circumstances a felon can be incised without discomfort. Whenever general anesthesias can be avoided it is a wonderful event and marks a step in progress. Dr.

Lee said that in treating cases of cholera at St. Petersburg by hypodermoclysis, in which a large quantity of salt solution was injected into the skin, it was found that anesthesia was produced and this is evidently the original observation in the matter.

No After-Pains.—In closing the discussion, Dr. Gant said that while there is no bleeding during the operation, and the oozing afterward is very slight as compared to the cases in which cocaine is used, surprisingly enough the after-pain is also less with the use of plain water. It is not an unusual thing for patients to suffer considerable pain for several hours after operations performed under cocaine or eucaine. It seems not unlikely that the nervous excitement the drug produces causes a condition in which pain is badly borne. Hence the complaints, for patients operated on with water anesthesia do not complain in the same way, though they have had to submit to practically the same experience.

Removal of Adenoids.—Dr. Clarence C. Rice said, that the removal of adenoid growths from the pharynx was probably the most frequent of surgical operations. At a conservative estimate the operation was probably performed fifty times during the day in New York City. Nearly every American child that suffers from nasal catarrh and is liable to frequent colds with tendencies to earache, especially if these are complicated by mouth-breathing, is a sufferer from adenoid hypertophy. The better knowledge of this subject has led the physician to realize that they are the cause of false croup not infrequently, and that they produce a distinct predisposition to pneumonia and tuberculosis. The amount of space in the child's larynx is so small that even a small enlargement may produce great discomfort. Hence the necessity for the complete removal of these growths. This is all the more important, since the after-effects produced by them and the stupid look of the child, the failure to develop properly in intelligence, the tendency to the production of chicken breastedness, all show the necessity for removal.

Reasons for Failure.—Notwithstanding the frequency with which the operation is performed, it is not an unusual thing to find that the removal of adenoids is not followed by the relief of symptoms. Dr. Rice considers that the main reason for this is that the adenoids are not completely removed. For thorough removal, the child must be under general anesthesia and care must be taken to see that every portion of the growth is removed. Attempts to do the operation under cocaine are usually unsatisfactory, unless in adults. Cocaine hardens the tissues and makes it difficult to detect just where adenoid hypertrophy exists, and besides, though the operation may not be painful, it still has most of its terrors for children, who are very much freightened at the manipulations and the bleeding. Physicians will say that the removal of adenoids is an easy operation, and he who acts on this supposition is almost sure to fail. Adenoids are sometimes said to recur, but the real explanation is that they were incompletely removed and the previous hyperplasia continues in the portions left.

Faulty Instruments and Technic.—The main reason for the failure of relief of symptoms is that instruments devised for the removal of adenoids are often faulty. They should be carefully selected to suit the individual case, and the curve in them should be laid down on anatomical lines. It is sometimes considered that if a large portion of the adenoid tissue is removed this will lead to the atrophy of the remaining tissue. But this is not true. In young children practically the only place where adenoid tissue occurs is in the pharynx and the posterior nares. In children between five and fifteen years, however, the hypertrophic process extends some distance down the pharynx and is likely also to have processes around the entrance to the Eustachian tube and along the pillars of the pharynx. For the removal of all this pathological tissue patience is needed.

Dr. Jarecki, in opening the discussion, said that general practitioners of medicine must not forget that there are some other causes for noisy breathing, and for snoring, than the presence of adenoids. In not a few of the cases in which operations for the removal of adenoids have failed to bring relief of symptoms, the reason for the failure has been that there were no adenoids present before the operation. The general condition of some of the little patients is responsible for some of the nervous symptoms and the noisy breathing, and if care is taken to improve the general health, they get well.

Position for Removal.—Dr. Quinlan said, that the best position for the removal of adenoid overgrowths is the upright. In this way the patient is less likely to inhale material and, besides, all the tissue under the influence of gravity hangs down into the vault of the pharynx and the surgeon can readily get at it for removal. There is good drainage into the stomach, and with an expert anesthetist there need be no fear about the effect of the anesthesia. In a number of operations done in this way, Dr. Quinlan has never seen any serious hemorrhage.

Cerebrospinal Meningitis Epidemic.—Dr. Henry Dwight Chapin presented some notes on the present epidemic of cerebrospinal meningitis. This disease is practically always endemic in New York. But early in March it began to increase. During the past ten weeks or more, the disease has occurred at least ten times as frequently as during the corresponding weeks of the last year. The epidemic has given a series of cases that are very irregular in their course and for which no clinical picture can be presented. The onset in most cases has been fairly abrupt, and in this the cerebrospinal meningitis differs from tuberculous meningitis. Among the first symptoms are vomiting and chills, which may go on to actual rigor. The severity of the onset is an indication of a serious prognosis. There are exceptions to this rule, however, and while stupor and coma early in the case usually mean a fatal termination, unexpected recoveries take place. Headache is extremely common, and the retraction of the head is a typical symptom. This rigidity may go on to opisthotonos. There may, however, be sudden improvement and even a tendency to sudden variations. Convulsions may be present up to the fourth or fifth day, but are unusual later.

Nervous Symptoms.—General hyperesthesia usually exists as in all meningitises. Great irritability, however, passes on into coma before very long, as a rule. Kernig's sign, as also Babinski's sign, are of some value, and Kernig's is almost constantly present. Very high temperature, due to nervous disturbance, is very frequent. A temperature of 106° to 107° F. by no means precludes the possibility of recovery. Sometimes temperatures drop very rapidly. In one case Dr. Chapin saw a drop of nine degrees in about ten hours. Other symptoms may be very severe and yet recovery take place. The patient with double neuroretinitis recovered. Involvement of the special senses through the nerves leading from the brain is

very common, as the result of the neuritis set up permanent crippling of the senses may be produced. The nervous symptoms are very often relieved by lumbar puncture and this constitutes the only sure means of diagnosis in mild cases.

Possible Contagiousness.—It is not known whether the disease is contagious or not. It does not seem to spread, however, from one patient to another. It is impossible to trace any sure connection between successive cases of the disease. While it is said to occur usually among the poor and in crowded quarters, this epidemis has invaded practically all sections of the city. The disease usually spreads during cold weather.

Eye and Ear Symptoms.—Dr. Pooley, in the discussion said, that occasionally the eye and ear are affected at the beginning of the disease, and then the cause of the local symptoms is metastasis from within the cranium. Later a true neuritis is set up which travels along the cranial nerves. The metastatic affection produces an iridochoroiditis and not a neuroretinitis. Usually this complication affecting the ear produces permanent deatness. A loud persistent tinnitus is often complained of and if the patient convalesces while the ear affection is still in existence, some unsteadiness of gait is seen. Not infrequently both ears are affected, and the patient is left totally deaf. Sometimes one eye is spared.

Diplococcus Intracellularis in Otitis.—Occasionally in the pus from an operated case of otitis media a diplococcus resembling Weichselbaum's meningococcus is found. This is apt to cause alarm at first, lest the meninges should be affected, and the otitis be only secondary. It seems evident, however, that this micro-organism is much more common than has been thought. Unless these cases have presented symptoms of meningitis before, meningitis never develops. The meningococcus may be as common in the air as is the pneumococcus, but requires certain conditions favorable to its growth before it seriously invades the organism. It is possible in certain cases of otitis for the epidemic cerebrospinal meningitis to be the cause of this complication, and yet have run so mild a course as not to be recognized until the peculiar set of symptoms caused by it are found to be already in existence within the ear.

HARVARD MEDICAL SOCIETY OF THE CITY OF NEW YORK.

Regular Monthly Meeting, held Saturday, May 28, 1904.

The President, Charles G. Schram, M.D., in the Chair.

Double Epididymitis.—The scientific business of the evening began with the presentation of cases, and Dr. Follen Cabot presented a case of double epididymitis. There was distinct thickening and induration, especially of the tail of the epididymis, and the indolence and comparative non-progressiveness of the affection seemed to point to a tuberculous origin. There is some question as to whether ill-advised injections given for the discharge that was very slight may not have had something to do at least with the condition on which the tuberculous process developed.

Double Inguinal and Femoral Hernia.—Dr. Ramon Guiteras presented for Dr. John B. Walker a case of radical operation done for double inguinal and femoral hernia. The inguinal hernia had been operated upon first on both sides, and when the patient sat up double femoral hernia developed. The child is five years old and the results obtained from the double operation have so far been very satisfactory.

Functional Albuminuria.—Dr. J. Bergen Ogden described a case that he considered to come under the head of functional albuminuria. This symptom-complex, for it does not seem to be a disease, has sometimes been called physiological albuminuria. There are many clinicians, however, who object to the term physiological albuminuria, since by no physiological process can albumin find its way into the urine from the blood. The objection may be far fetched and yet, as was pointed out by most of the authorities on the subject, in the discussion held before the London Clinical Society, in December, 1903, functional is a better word, because a more non-committal term than physiological albuminuria. Sir William Broadbent favors the term postural albuminuria, as the appearance of albumin in the urine absolutely depends on the position of the patient. While there is no albumin in the urine during and just after the time that the patient is lying down, it makes its appearance invariably after he has been standing for some time, or after he has taken some exercise. This form of albuminuria is also spoken of as cyclical, or the albuminuria of healthy persons. The albumin is usually absent from the urine in the early morning hours, but it increases in amount as the day advances, having its maximum usually at night.

Albuminuria of Adolescence.—The symptom-complex has been observed most frequently in boys under twenty years of age, and so is often spoken of as the albuminuria of adolescence. It seems to have some connection with the systemic development going on about this time and with the drain on nutritional resources which so often causes disturbance of the blood, giving rise to the characteristic ailments of this period in young men as well as in young women. It seems to occur most frequently in those who do not take much exercise or who take their exercise by fits and starts. There is an absence of organic lesions and the albuminuria is usually discovered as the result of an insurance examination or because of some curiosity or accidental urinary examination for some purpose. The patients never have any cause for complaint in their general health, have no special sense of weakness and no tendency to any of the serious effusions characteristic of the albuminuria of kidney disease.

Etiology.—There seem to be two causes for the affection. The first is muscular exercise and the second unsuitable diet. Senator and Granger Stewart thought that it was sometimes due to an especially rich proteid food consumption. That it was a sort of alimentary albuminuria due to a superabundance of albuminous food just as alimentary glycosuria may be produced by too great indulgence in sugar-containing food. In Dr. Ogden's experience, however, any abundance of diet seems to be causative of it. Usually it has been noticed that there is an increase of tension in the pulse. Often a violent cardiac impulse has been noticed. An increase in the blood pressure within the kidney is then supposed to be responsible for the leaking out of some of the serum albumin from the blood.

Hypertrophy of the Right Ventricle.—Sir William Broadbent says that in all the cases in his experience the left ventricle has been rather weak but the right ventricle has been hypertrophied, and that

while the apex beat was not specially strong, the valve sounds over the right ventricle could be heard with much more distinctness than normal, while those of the left side of the heart were rather weaker than normal. In the experience of others the second sound of the heart has been reduplicated, probably because of a failure of the valves on the two sides of the heart to act at the same moment in accentuation of the valves of the right side. The circulatory system is the underlying causative factor for the functional albuminuria. It may be said at once, however, that the condition of the blood vessels of the kidney, which allows the passage of albumin through them, is not understood, nor does there seem to be any way of appreciating what the leakage may be attributed to.

Illustrative Case.—Dr. Ogden's patient was a young man of twenty years, a laboratory worker, whose mother died of some kidney trouble and whose father had suffered from heart disease. He had noticed, one day, while examining his own urine, out of curiosity, that it contained some albumin. Physical examination then was made, and while his apex beat was found to be strong and forcible, his heart was not enlarged and no difference could be detected between the action of the two sides of the heart. The young man was rather nervous and excitable, he blushed easily and there was a tendency for easy disturbances of the cutaneous circulation. More careful examination of the urine showed occasionally hyaline casts with some red blood cells, but not enough to be considered of serious import. The cause of the condition was then looked for, and as there was marked oxaluria his diet was carefully inquired into in the hope of finding the etiological factor. It was found that the young man was living on the outskirts of Brooklyn, where the city water was not yet distributed, and drank a considerable quantity of root beer. This was considered to be probably the cause of the appearance of oxalates in the urine. After he had ceased taking it for some time no further large primary crystals of the oxalate series were formed, though some secondary crystals of oxalates were present. The only treatment suggested was an abundance of water and care with regard to his diet. As the result of this régime all the formed elements in the urine gradually disappeared but the albumin constantly remained. In six months, except for the presence of albumin, at most only a trace (about one-twentieth of one per cent.), the urine was absolutely normal. Hourly specimens were then examined, and it was found that the first specimen in the morning contained albumin. An hour after the patient's rising from bed, however, albumin appeared and continued to be present all during the day, reaching a maximum at night. The patient was asked to examine his urine himself before getting up, and found that urine passed every hour from five till eight in the morning, while he was lying in bed, was absolutely free from albumin, though within an hour after he got up albumin was present. The boy was perfectly well and felt no inconvenience of any kind, notwithstanding the presence of these urinary symptoms.

Result of Exercise.—On Mondays, after the boy had taken considerable exercise on Sunday, albumin was more abundant than on other days during the week when this exercise was limited to the ordinary walking around in the laboratory with light work. Under instructions he lay down every afternoon for four hours on several successive days, between twelve and four. After the first hour no albumin appeared in the urine, though it made its appearance promptly after he got around on his feet again. The limitation of his food seemed to make no difference, for when he went without lunch the albumin continued to be present in the same way. The young man was never a very hearty eater, ate considerable bread, and not very much meat or eggs. In this case then the diet seems to have had little if any effect on the production of the albumin in the urine.

Change of Occupation.—After a time he resolved upon a change of occupation and became a carpenter's helper. This kept him out of doors most of the day and gave him much more strenuous exercise than before. His general condition began to improve at once under this, and within a month he gained ten pounds in weight. Notwithstanding the fact that before this exercise had apparently always increased the amount of albumin in his urine, the exercise now taken did not seem to prove harmful. Careful examination showed that the amount of albumin was not larger than before, but, if anything, was a little less. The young man has continued to improve in health and feels ever so much better than he did when his occupation kept him indoors so much of the time.

Typical Functional Albuminuria.—Dr. Ogden considers that this is a typical instance of functional albuminuria. The albumin present was serum albumin, and no globulin or albumoses were found at any time. The specific gravity of the urine was on an average about 1.021. It varied between the extremes of 1.012 and 1.029. The uric acid was about normal and the urea a little above the average. There is, of course, the question of the root beer in the etiology of the irritative condition of the kidneys which seemed to be present when the urine was first examined. The root beer seemed to bear a definite relation to the oxalates found in the urine, and Dr. Ogden considers that it was certainly the cause of the oxaluria. This was due either to the fact that the fermentative process produced oxalates in the liquids which were absorbed, or their presence in the digestive tract led to intestinal fermentation, with the production of oxalates which later appeared in the urine.

Favorable Prognosis.—The prognosis in most of these cases is not at all unfavorable. Sir William Broadbent says that in a large experience with postural albuminuria he has never seen unfavorable symptoms develop from it. Pavy says that he has watched cases of functional albuminuria for fifteen years and they have not, in that time at least, proved to be the beginning of nephritis. The treatment for them consists mainly of fresh air and exercise. Patients especially need to be out much more in the air than they have been before, and the attending physician must be careful not to cut off their exercise, as he might be tempted to do, since exercise increases the amount of albumin in the urine, but rather to encourage the taking of regular but not violent exercise. It is important, of course, to allay any nervous symptoms that patients may have as the result of having been refused by life insurance companies or having been told by some too zealous physician that they have albumin in their urine.

Treatment.—The treatment consists in the improvement of the general condition rather than in

any special attention to the kidneys. Tonics such as iron, arsenic and quinine can be used with benefit. Too much care with regard to the diet by constantly calling the patient's attention to the possibilities of his case is apt to do more harm than good. Some of the English authorities in the recent discussion before the Clinical Society of London cited cases in which insistence on a milk diet, with the idea that the albuminuria was due to kidney disease, which might be alleviated by absence of all irritation of the kidneys, gave rise to nervous symptoms which became very obstinate to treatment after persistence in this insufficient nutrition for some time. Dr. Ogden's own case shows the necessity for removing from the dietary any article that is especially suspicious, such as seemed to be the root beer, and then the advisability of outdoor life with sufficient exercise to give a good, healthy appetite.

Dr. Follen Cabot said that physiological albuminuria is not so infrequent as has been thought. Usually the risks refused by insurance companies have passed beyond the point of what may be called true physiological albuminuria. Even where mild cases of nephritis are discovered now, quantitative tests in order to ascertain the amount of insufficiency of the kidneys are made, and especially the solids in the urine are studied with the idea of giving the patient a chance to become a substandard risk and not to be refused absolutely.

The Right Heart and Functional Albuminuria.—Dr. Charles G. Schram said that Broadbent's sign of the increased activity of the right heart should prove a valuable diagnostic aid. In ordinary nephritis there is of course an hypertrophy of the left heart, with distinct increase of the sounds on the strength of the apex beat. Dr. Schram had a case under observation for some three to four years in which the amount of albumin present is about one-eighth of one per cent. In all other respects the young man, who is not yet twenty, seems perfectly well. His attention was called to his condition when he, to his astonishment, was refused by a life insurance company. After careful study of the case of some months Dr. Schram suggested the advisability of reapplying to the insurance company and gave a certificate attesting his disbelief of any true nephritis being present. The case was not accepted except as a substandard risk.

Rapid Growth and Movable Kidney.—Dr. Ernest Gallant said that functional albuminuria seems to occur with more frequency in young persons who grow rapidly and are not of very strong constitution. Some neurasthenic symptoms are likely to accompany it. After growth has been attained the condition may pass off, though sometimes the habit seems to be formed and the slight albuminuria continues. On the other hand, a certain amount of albuminuria is quite common in patients suffering from movable kidney, even though but to a very small degree. In these cases there are apt also to be some formed elements in the urine. Slight amounts of movable kidney are not infrequent in young persons who have acquired their growth rapidly, and these two conditions should be borne in mind in connection with this affection.

Dr. Ogden, in closing the discussion, said that in his case the kidneys were not palpable nor movable on careful examination made in both the lying and standing positions. Most insurance companies reject these cases but they seem scarcely to be justified in so doing. The improvement of the condition, apparently made worse by exercise, when exercise was taken as an habitual occupation is the most interesting feature of the affection.

General Cardiac Hypertrophy.—Dr. Charles G. Schram presented a patient suffering with general hypertrophy of the heart and with possible aneurism. The patient was a man of fifty-two years, whose father died at fifty-eight years and whose mother at fifty-five years, and whose own personal history was excellent. From his earliest childhood he had not suffered from any of the infectious diseases and had not rheumatism and denied all venereal history. A brother suffered from gouty deposits in the ear and fingers and toes, but the patient had never suffered in this way. When about twelve years of age he began to work in a hotel, taking as far as he was able to the duties of porter. He carried heavy bundles up and down stairs to the limit of his strength and, as elevators were not much used at the time, had to do much more carrying than is usual at the present time. When he was about eighteen years old his mother noticed a bulging of his left chest. He had never noticed this before. This gave him no inconvenience, however, and he continued to work hard for six or seven years more. At twenty-five he became a butcher and worked at this for twenty years, as a rule devoting eighteen hours a day to it. In this he also had to do a large amount of heavy lifting. He never suffered from any symptoms of shortness of breath or the like and considered himself a healthy man. About seven years ago, having acquired a competency, he settled down to a quiet life.

Development of Symptoms.—About two years ago he began to lose strength and to suffer from dyspnea. At the same time, he coughed considerably and brought up abundance of sputum. He could not rest in bed and had to sit up all night and rest on a chair. His appetite was good, however, and his general condition otherwise not very much disturbed, until about six months ago, when he began to suffer from edema with increasing cyanosis and other signs of failing heart. When he came under observation his lips and fingers were quite blue, and the number of fine, crackling râles at the bases of both lungs showed the existence of a hypostatic condition from disturbance of the circulation. A distinct bulging was found to exist over his left chest, beginning at about his second rib and extending to his sixth. The cardiac impulse was somewhat diffuse in both the fifth and sixth interspaces about one inch outside the mammary line. On the right the heart dulness extended to about an inch beyond the sternum. Relative heart dulness could be demonstrated just below the second rib and absolute dulness just below the third. No thrill was perceptible at any point over the cardiac area. Owing to the pulmonary condition it was expected that the second pulmonary sound would be found accentuated, but it was not. The only murmur to be heard over the heart was systolic in time, heard most plainly over the mitral area and conducted around into the axilla, so as to be heard even at the back. The general heart condition seems to be one of hypertrophy with some dilatation, this latter factor being important in the production of the signs of failing circulation and being probably of comparatively recent orgin.

Suspicion of Aneurism.—The possibility of aneurism in this case can not be absolutely excluded. If there were dilatation of the ascending aorta it might

well push the heart forward against the chest wall, and its presence might lead to the hypertrophy which the enlarged dulness testifies. The cause of the condition is evidently the heavy lifting to which the patient was subjected at a very early period of his life, when he was scarcely more than a child, and which led to the hypertrophy of his heart with perhaps the consequent yielding of the front wall of the thorax over the organ. The stages of the affection can be traced rather readily. During adolescence there was naturally a prompt compensatory hypertrophy to make up for the work required of the patient, at the same time that his growth was making calls upon his circulatory system in other ways. During adult life his compensation was excellent. At about the age of fifty years his compensation began to give out. Two years later it broke down completely and the pathological picture presented itself.

Treatment.—The patient was put on a regimen including regular exercise with a large amount of rest. He was advised not to take much fluids and very little food in the evening. Besides this he was given tincture of iron rather freely in the shape of Squibb's preparation, which in Dr. Schram's hands has always given excellent results. For short periods he was given infusion of digitalis and during the intervals iodide of potash. This latter drug seemed to lower arterial tension and lessen the feeling of discomfort. Under this regimen the patient rapidly improved and now sleeps much better, is not troubled with the persistent cough that was formerly so annoying; he has a better appetite and generally considers that his condition was so much improved that life looks reasonably hopeful once more. There seemed no reason why, under a continuance of careful attention to the details of life, especially exercise, rest and diet, the patient should not continue to be in good condition. His circumstances are extremely favorable for therapeutic purposes. He has no duties that are imperative; he has no source of worry, and he can regulate his life absolutely as he likes and live where he will. The prognosis, therefore, of the case is good.

Child Labor and Athletics.—Dr. Schram considers that this case is an excellent example of the evils of child labor. When during the developmental period strains are put upon the heart, the results are almost sure to be seen in hypertrophy with subsequent degeneration of that organ. Nearly the same thing happens, however, from overindulgence in severe athletic sports, such as is only too often the case in preparatory schools and colleges at the present time. Growing youths are tempted to make supreme efforts for the glory of their school or college or for their own personal vanity and the result is hypertrophy of the heart.

Hodgson's Disease.—Dr. James J. Walsh, in discussing Dr. Schram's case, said that in certain respects it resembles a symptom-complex described by an English physician of about a half century ago, after whom this type of affection is sometimes known as Hodgson's disease. The affection consists of a dilatation of the beginning of the aorta, just as it leaves the heart. This dilatation of the conus arteriosus is not really aneurismal in character, nor in the cases so far observed has it ever given rise to aneurism. It usually causes the apex beat to be displaced somewhat downward and outward, and brings the arch of the aorta much nearer to the finger applied in the suprasternal notch between the sternocleido muscles than is usually the case. An area of dulness to the right of the sternum in the neighborhood of a second rib is also usually a concomitant symptom. The murmurs occurring in the disease are irregular, though usually there is a systolic murmur at the aortic orifice. The cases are irregular in type, and it is not impossible that further study might show that this is really a case of so-called Hodgson's disease.

Congenital Anomaly.—Dr. Stephen Burt suggested that the bulging of the chest anteriorly in the heart region might be congenital. The fact that the boy himself had not discovered it until it was pointed out by his mother was, in itself, no proof that it had been acquired, since such malformations often escape the notice of young people. The heart affection would then be the result of the strain in early youth, though perhaps not connected with the chest deformity.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, held June 2, 1904.

Section on Obstetrics.

The Chairman, Palmer Dudley, M.D., in the Chair.

The scientific business of the evening was opened by the presentation of specimens.

Internal Pseudohermaphroditism.—Dr. Ladinsky, presented the specimens of a case of this rather rare condition. The patient from whom they were removed was a woman of forty-six years, who had been married at about the age of twenty. She menstruated rather late, only beginning when nearly nineteen years of age and then flowing only a slight amount and irregularly. She suffered from epistaxis all through her life at irregular intervals. It was presumed that this was compensatory for menstruation. Examination in the vagina showed no cervix and on bimanual palpitation no uterus could be discovered. Examination by the rectum was equally unsuccessful in this respect. A smooth ovoid mass could be felt in the right labium. This was reducible and was considered to be a hernia. A radical operation was done and when the sac was removed a tissue resembling the broad ligament was found, and on microscopical examination portions of uterine tissue were discoverable. The picture, however, was extremely anomalous, and some testicular tissue could be demonstrated, as well as appearances resembling those of the corpora amylacea of the prostate.

Large Uterine Fibroid.—Dr. Ladinsky also presented a large fibroid tumor, which had involved the whole uterus, even the cervix. This special enlargement of the uterus simulated pregnancy. As the fibroid was rather soft, there was a deceptive feel as of fetal contents. The only proof of the non-existence of pregnancy was the continuance of menstruation and the frequent bleeding. In discussing this case Dr. Palmer Dudley said that these cases are not often as deceptive as this. It is not frequent to see large fibroids, as, fortunately, these tumors are removed before they become of large size. In most cases it is impossible to extirpate them by the morcellement, and the uterus need not necessarily be removed. In such cases, however, there should be thorough drainage, and to avoid the danger of subsequent sepsis the uterus should be thoroughly curetted beforehand and then swabbed out with pure carbolic acid.

True Hermaphroditism.—Dr. Palmer Dudley said that some years ago he had seen a case of that rare

Dr. L. J. Hammond, in the discussion, said that this very instructive case is the exception, not the rule, in ovarian cystoma, the typical fluid found being characteristically straw-colored. This chocolate-colored contents is not uncommonly found in the broad ligament cysts of the paroophoritic type. It is instructive, therefore, to note this condition of papillomatous change existing in ovarian cysts. These masses, as described in this specimen, might readily account for the blood-mixed fluid found in such large quantity in the cyst.

Dr. Formad said that this was not a broad ligament cyst, but an ovarian cyst. This was shown by the microscopical examination.

The Ultimate Results of Induced Labor for Minor Degrees of Pelvic Contraction.—Dr. Richard C. Norris read a paper with the above title and reported in detail thirty cases, with their results for mother and child, the degrees of contraction varying in the conjugate diameters between eight and ten cm. There was neither maternal mortality nor morbidity. The infantile mortality was ten per cent., after following the histories of the children subsequent to their leaving the hospital. Dr. Norris took issue with those who recommend hasty Cæsarean section for these grades of deformity. He quoted Williams's statement that hardly more than 50 per cent. of the infants survive the first few months of life, and said that that statement could only be true of induced labors for high grades of contraction, a field no longer to be tested by labor, but by elective Cæsarean section. He also referred to Reynolds's statement that Cæsarean section is indicated when, with any definite pelvic contraction, there is a history of repeated childbirths during previous operative labors, and for healthy primiparæ with conjugates between three and four inches; that the amount of difficulty which will occur should be estimated by observations of the progress of labor; but that the possibility that an indication for the Cæsarean section may arise would always be borne in mind in such a case, and that all the preparations for it should be made beforehand, or at least during the first stage of labor. Norris referred to his tables, and asserted that it was just in such cases that his best results were obtained by induction of labor, not more than four weeks and usually two weeks before term. The assistance given nature by skilful induced labor, and the employment of the Trendelenburg-Walcher posture, had repeatedly avoided the necessity for a difficult operative delivery, which ordinarily gives the high fetal mortality. He discussed the difficulties of accurate estimation of the duration of pregnancy, and outlined the plan he followed to eliminate as far as possible the induction of labor at too early or too late a period of pregnancy. An analysis of his tables of thirty cases was presented, and a plea made for the adoption of this method of treatment in place of the hasty and oftentimes spectacular Cæsarean section, which, in his judgment, had sometimes been an exhibition of experimental and unnecessary surgery.

Dr. George M. Boyd, in the discussion, said he felt that the profession ought to thank Dr. Norris for bringing this interesting subject before it. While Reynolds may do a long series of Cæsarean sections, and Norris still another series of induction of premature labor without death, there will be cases of death from Cæsarean section and from induction of premature labor. Dr. Norris, however, is to be congratulated upon his results, which show a much lower fetal mortality than many of this society have enjoyed. It has been the high fetal mortality which has caused many to refrain from performing the induction of premature labor. In Dr. Boyd's experience, following the Lying-in Charity for fifteen years, he confesses that he has only in exceptional cases resorted to induction of labor, because of his inability to measure the length of gestation. It seemed to him there must almost always exist a latitude of two or three weeks,, and it is just that latitude that makes the operation an uncertain one. If the operation is of any real benefit, it must be done sufficiently early. Then, again, the operation itself is an uncertain one, because some patients will go into labor right after the introduction of one or two bougies, and other patients not until after many hours. In some cases he has seen the unfortunate rupture of the membranes with the best operators. There is some danger, also, of striking the placental site, and some slight danger from infection, so that, fearing the early rupture of the membranes, he has preferred to allow his patients to go to term. He feels that the only really accurate way of measuring the pelvis is by the test of labor and noting whether the head is or is not adapting itself to the birth canal. As far as his experience goes, he feels that the patient would be best served by permitting her to go to term, and, after the test of labor, resorting to the operative measures that seem best indicated.

Dr. Daniel Longaker said that the subject under discussion is one of considerable importance, and he thinks the society is fortunate in having such an able exposition of the matter as that given by Dr. Norris. It seemed to him (Dr. Longaker) that the indications for this particular operation are clearly set forth in limiting the induction of premature labor to the lesser degrees of pelvic contraction. Going back some considerable time in his own experience, he remembers different cases in which the operation of induced premature labor was ill-advisedly applied to degrees of pelvic narrowing which were entirely too great to permit of even the safe delivery of a child that had only reached the twenty-eighth week of gestation. For instance, a child that had not attained a weight of more than 5½ pounds and as nearly as could be determined a period of gestation of twenty-eight or thirty weeks, with a difficult extraction in a woman whose direct conjugate was estimated to be 7½ cm. or a little under, too great a degree of contraction to permit safe extraction, and the child had to be delivered by version. If one selects the operation for that class of cases, it must fall into disrepute. That particular woman was safely delivered twice after that by symphysectomy of a living baby of large size at term. The cases in which induced premature labor will have brilliant results are the lesser degrees of contraction, the direct conjugate being not under eight cm. Dr. Longaker does not know whether he is correct in his conclusion, but his impression is that in these cases there is a tendency, for some reason which he does not care to discuss, to protracted gestation. He has knowledge of cases which have been pretty carefully studied in which the gestation has gone to almost three hundred days, twenty-eight to thirty days beyond the computed time, and where the size of the child was an additional evidence that it had been carried beyond the average time. He thinks that where one has reason to know from external measurements and from the history of preceding labors that there is pelvic contraction, it behooves

him to watch the case with extreme care and to estimate not only the size of the pelvis, but the size of the fetal head, which can best be obtained by the Miller method. In a case of this kind one should not allow the gestation to be contracted, and much will be gained by timely interference.

Dr. William R. Nicholson said it struck him that the induction of premature labor is one of the most useful obstetrical procedures, since the smaller grades of pelvic deformity are the common ones met with. It seemed to him that to allow a woman with a contracted pelvis to go into labor with her first child, to determine whether she can give birth to that child spontaneously is in certain cases a pretty dangerous method to follow, unless the patient be of the best class of society, since in certain grades of practice it is not possible to do Cæsarean section in private houses. He thinks Dr. Boyd has stated all the possible objections. The only thing that occurred to Dr. Nicholson, in listening to Dr. Boyd, was that a man who was unfit to put in a bougie, so far as sepsis was concerned, was unfit to do a Cæsarean section. While he has not induced labor 100 times, he has never seen the slightest difficulty in regard to the rupture of the membranes, and has never had a case which has shown temperature after the bougie was in place, unless the induction was prolonged and the membranes ruptured.

Dr. R. C. Norris spoke about the difficulty of estimating the duration of pregnancy. He would like to ask Dr. Boyd, when he predicts for his patients the probable date of confinement, how many times his patients go three or four weeks over that time? He does miss it once in a while, but in his hospital and private practice he finds pretty accurate estimates made. When the estimates have been inaccurate, he has explained the error in two ways: Either the woman herself has made a mistake in her recollection of her last period and of the date of quickening, or she was that type of woman who conceives just before her first missed period rather than just after her last period. The estimation of the duration of pregnancy is not difficult when one has a reliable history. It is usually in the lower classes that the women forget or disregard the date of their last sickness, and in these cases he admits it is often difficult to determine the duration of pregnancy solely by fetometry. You cannot do so as accurately as by the history of menstruation and quickening. All these facts should harmonize—the history of menstruation and of quickening and the estimated size of the child and height of fundus. He has known the advocates of hasty Cæsarean section to make the same error in calculation, and to deliver six-pound babies that have to be put in incubators. The plea of his paper is emphasized by Dr. Longaker, when he speaks of confining this discussion to minor degrees of pelvic narrowing. The period of time required for the determination of an induced labor has varied from six and a half to sixty-four hours. The rubber bag is of the greatest value. The bougies used alone often will not be efficient. He remembers Dr. Parvin on one occasion at Blockley putting in a series of bougies which remained for a week or so without bringing on pains. In cases of that kind, the rubber bag is essential, and in his (Dr. Norris's) cases he accomplished the result in an average of twenty-nine hours and without danger of sepsis. Premature rupture of the membranes when passing the bougie carries with it a certain amount of danger. Partial separation of the placenta he has noticed several times, but never with an ill effect upon mother or child. The danger of infection is a matter of individual equation, and depends upon one's aseptic technic. The test of labor is justifiable in most degrees of pelvic deformity that come to one, and he does not see any disadvantage if the labor is brought on two to three weeks before time. You have a smaller baby's head, and if the test shows that she is going to fail, you are in a better position to do version or use the forceps with a baby two weeks under its time than with a baby ten days or two weeks over its time. He has read nothing in literature, or heard any remarks from men doing frequently the Cæsarean section for the same grade of cases that would make him change his position, and his own records carefully studied have convinced him more than ever that many Cæsarean sections can be safely avoided by skilled induction of labor.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Fifty-fourth Annual Meeting, held at Pittsburg, September 27, 28 and 29, 1904.

FIRST DAY—SEPTEMBER 27.

This meeting was called to order at 9.30 A. M., in Music Hall of Carnegie Institute, by the President, Dr. William B. Ulrich, of Chester.

Prayer was offered by the Rev. Dr. McIlvaine, which was followed by addresses of welcome on behalf of the citizens of Pittsburg by Mr. J. A. Blair; on behalf of the Allegheny County Medical Society by the President thereof, Dr. T. M. McKennan, in which he reviewed the progress made by both the Allegheny County Society and the State Society, since the first meeting of the State Society in Pittsburg, about half a century ago. These were followed by an address of welcome by William J. Holland, Ph.D., LL.D., Curator of the Museum of the Carnegie Institute, in which he reviewed the life and work of Andrew Carnegie and commented upon his gifts to the city of Pittsburg.

Address in Medicine.—Dr. Henry Beates, Jr., of Philadelphia, said that medicine was essentially the consequence of cause and effect, and that the highest physical and mental health and character were necessary to a physician in order that he might properly execute the bond of trust existing between him and his patient. He dwelt upon the detrimental effect of the spirit of commercialism, which to some extent is invading the ranks of the professions, as well as the electropaths, osteopaths, etc., and urged the necessity for the education of the laity to the value of consulting only a qualified practitioner. He urged the necessity for the better fundamental education of the medical student before he is allowed to matriculate at colleges, and believed that only those should be permitted to enter who had the required preliminary education.

Address in Surgery.—Dr. Winters D. Hamaker, Meadville, dwelt particularly upon the disadvantages of the physician when sued for malpractice, assigning as reasons: (1) His prosecutor is in nearly all cases without property, and the juries know that the counties must pay the costs if the suit fails; (2) in many of the cases the poor results have been brought about by neglect or disobedience on the part of the patient or his friends; (3) before a jury a case may be made out worse than it really is or

can be "made up" entirely. (4) Courts will not allow an examination under an anesthetic to make a complete diagnosis. (5) The profession has devised no system of common defense. (6) The juries are ignorant of the subjects discussed. (7) So-called experts, very often ignoramuses, are brought in to testify against the defendant. (8) The impossibility of obtaining good results in many cases of severe injury. He urged that the surgeon in complicated cases should insist upon frequent consultation, X-ray examinations and strict obedience from the patient. Reference was made to the method of insurance companies issuing policies to physicians against such losses, and the Society recommended to consider the advisability of appointing a committee to investigate this matter as well as the securing of more favorable legislation.

Address in Obstetrics.—Dr. X. O. Werder, of Pittsburg, spoke on the Treatment of Pregnancy Complicated by Pelvic Tumors, in which he said that ovarian cysts, being a constant menace to the safety of the mother during pregnancy, should be promptly removed at any period of gestation; (2) pregnancy complicated by fibroid tumors should as a rule be treated on the expectant plan, and require interference only when serious danger to the mother arises; (3) when carcinoma of the uterus is discovered during pregnancy, immediate radical operation should be done, when the disease is still in an operable stage, regardless of the child. When the neoplasm is inoperable, however, the life of the child becomes the paramount consideration in the treatment.

Address in Hygiene and State Medicine.—Dr. Alexander C. Abbott, of Philadelphia, spoke of nuisances and places which, under improper care, might become such; the compilation of vital statistics, the management of contageous diseases and the establishment of hospitals for their reception, as well as maritime and, when necessary, inland quarantine. The scant mortality and vitality records in the rural districts, he felt, were in a large measure accountable for the fact that they were able to report lower death rates from certain diseases than the municipalities, and especially urged the value of vaccination as a preventive of smallpox. He also dwelt upon the necessity for more accurate vital statistics from the country districts where the cities received their milk and water supplies, and believed better results would be attained if the examination of the applicant for a license to practise medicine was directed more to bedside and laboratory demonstrations, and not so much to theoretical.

The Need for Systematic Study of Individual Characteristics as Manifested by the Organism's Reaction to Stimuli.—Dr. William K. Walker, of Dixmont, took this for his subject, in which he urged the importance of the individual study of each case, particularly the chemical and physical phenomena of nutrition and the vasomotor and secretory conditions.

Indicanuria Complicating Typhoid Fever.—Dr. Judson Dalland, of Philadelphia, referred to the various tests, and recommended modifications by which more accurate and uniform results could be obtained. He referred to the frequent association of the absorption of products of putrefaction in the intestines, with indicanuria, and dwelt upon its frequency in typhoid fever, based upon observations covering almost a decade. When this condition is present he strongly urged antisepsis of the mouth and persistent local treatment of any morbid condition of the nasopharynx and sinuses, believing that abnormal secretions from these regions, when mixed with food, especially milk, causes rapid decomposition and fermentation. He advised calomel, phosphate of sodium and the free use of pure water, occasionally alternating with vichy, and strict adherence to a peptonized milk diet, with the administration of broths twice daily. As a preparatory treatment, while the gastro-intestinal tract is being cleared of its contents, he recommends the exclusive use of animal broths, and when the indicanuria still persists, colonic irrigation, with one or two quarts of warm normal solution, introduced by means of a long, soft rubber tube. When ulceration is active, or there is any reason for believing that hemorrhage may take place, this treatment should be omitted; and, as a rule, he recommends its omission during the third week, unless toxic symptoms are serious.

SECOND DAY—SEPTEMBER 28.

Section B.

Progress in Treatment of Skin Diseases.—Dr. John R. McCurdy, of Pittsburg, reviewed the various remedies that had been employed, and stated that up until the middle of the nineteenth century there seemed to have been but little scientific investigation in the field of dermatology. He referred to the Roentgen rays and the Finsen light treatment, which he stated were yet in their infancy, and, in conclusion, urged a more scientific study and treatment of these conditions.

Treatment of Skin and Glandular Diseases by X-Ray.—Dr. Russell H. Boggs, of Pittsburg, said (1) technic is largely responsible for both successful and unsuccessful results; (2) in the treatment of lupus, epithelioma, carcinoma, acne, eczema and tuberculosis, the X-ray is an excellent remedy; and (3) in most cases of carcinoma the combination of X-ray and surgery offers the best chances of recovery. He dwelt particularly upon the importance of dosage and the persistence of the treatment after the apparent termination of the disease, and reported the result of twenty-seven cases of lupus-vulgaris, two cases of lupus erythematosis, thirteen cases of primary epithelioma, and several cases of acne, chronic eczema and birthmarks.

Roentgen Rays and Radium Therapy.—Dr. Mihran K. Kassabian, of Philadelphia, said that after conducting a series of experiments at the Philadelphia Hospital, to determine the comparative value of the two agents, in some cases using them on different parts of the same growth, he had discovered that the radium produced little or no effect, and had therefore discarded it for the Roentgen rays. Epitheliomata, he stated were the most satisfactory cases; and in carcinoma it was recommended that operation precede the application of the rays. Twenty cases of chronic senile leg ulcer, some of which have entirely healed and all improved, were reported, as were also fifteen epileptic cases of the insane department of the Philadelphia Hospital, in which the frequency and severity of the attacks had lessened under the Roentgen-ray treatment. He illustrated his paper by numerous photographs and lantern slides.

The Treatment of Malignant Diseases of the Breast.—Dr. Charles Lester Leonard, of Philadelphia, and (1) that our knowledge of the etiology and pathology of the disease is very limited; (2) the natural benignity of atrophi scirrhus is apparently

explained by certain pathologic changes that show an attempt by nature to retard the progress of the disease; (3) the results produced by Roentgen treatment are practically identical with this natural process, but are more complete, showing a power over the malignant cells themselves; (4) conservative surgery tends toward a non-operative treatment of hard cancers (atrophic scirrhus) and their treatment by X-rays; (5) early radical removal by surgical operations is indicated in all other primary growths and operative recurrences to be followed by early Roentgen treatment, the value of which, however, depends upon the skill and experience of the operator.

Inhibitory Action of X-Ray Upon Malignant Growths.—Dr. George C. Johnson, of Pittsburg, said (1) the radiation from an excited Crookes tube is capable, when properly applied, of inhibiting malignant growths, that such inhibition is dependent upon the skill and experience of the operator, and may be complete and permanent as to produce a clinical cure. It may be applied as a palliative remedy in inoperable cases, and in cases unfit for operation it may be used as a tonic treatment, and is also of great value as a postoperative measure; but the employment should be confined to the hands of competent physicians and surgeons experienced therein.

Knee Anchylosis.—Dr. DeForest Willard, of Philadelphia, stated that it was a condition, the result of a disease and not a disease itself, and may result from many different pathological conditions. He remarked that the discovery of the cause was all-important, as the determination as to the treatment to be pursued after the joint has become fixed must depend, first, upon the cause, and, second, upon present joint conditions as discovered by careful clinical examinations, aided by X-rays. The author outlined the appropriate treatment for anchylosis following gonorrheal infection, septic infection, tuberculous disease, or with suppuration, and cited as the accidents most liable to result from forcible straightening, fracture, posterior dislocation and aneurism.

Modern Methods for Combating Deformity in Spinal Caries.—Dr. David Silver, of Pittsburg, said that the complicated nature of the spine rendered treatment of deformity difficult. Traction by suspension, as a means for correcting the deformity and placing the spine in the proper position for fixation is deficient because (1) it does not separate the diseased vertebral bodies, and so does not abolish the traumatism from weight-bearing and functional uses; (2) the force is largely expended upon the secondary curves, the kyphosis being slightly modified; (3) a large part of the good effect is lost unless traction is made continuous by means of a head support. Similar objections apply to recumbency on a flat surface. Hyperextension he considered the best method and the best procedure for obtaining correction and for the routine application of the jacket of the Metzger-Goldthwaite frame.

The Relationship of the Femur to the Pelvis.—Dr. Stewart L. McCurdy, of Pittsburg, said that the transpelvic lines crossing the pubic spines will cross the trochanteric eminences in children, and above the same point in adults, and when the trochanter is found above this line, displacement from some cause is always present. Disregarding the pubic spines, two lines may cross the pelvis, one through the anterior superior spines and a second through the trochanteric eminences. If these lines are not parallel, then the displacement exists on the side on which the lines converge or are closer.

Section A.

Drugs vs. Other Methods of Treatment.—Dr. T. W. Grayson, of Pittsburg, treated of the present tendency among physicians to give more and more attention to the use of diet, electricity, massage, baths, hygienic measures, ventilation, rest, and active or passive exercise in the treatment of disease, and not to depend so exclusively as formerly on drugs alone. Text books show this, and it is illustrated when one considers how in the past few decades much besides drugs has come into use in the treatment of tuberculosis, gastro-intestinal diseases, malaria, rheumatism and typhoid fever. The author did not wish to be classed among the "therapeutic nihilists," but emphasized his thought that often a certain drug may suit the case quite well, but a better remedy is found in correction of faulty habit or in the use of hygienic measures much harder for the physician to find and prescribe, and more troublesome to the patient to use than in a bottle of medicine or a few tablets.

Asthma—Its Varieties and Treatment.—Dr. Solomon Solis Cohen said that no condition exhibits so many individual peculiarities as asthma, and that in none must the physician have more strings to his therapeutic bow. Asthma he declared to be a group of symptoms and not an independent disease. The diagnosis was therefore incomplete until the underlying affection giving rise to the symptom group is discovered. On the other hand, when definite lesions in the heart and kidneys exist and so-called cardiac and uremic asthma supervene the condition is not usually pure asthma, but dyspnea dependent upon heart failure, sometimes, it is true, aggravated by the presence of uremic toxines. True asthma presents clinically four varieties: (1) Asthma dependent upon vasomotor ataxia; (2) asthma dependent upon bronchial spasm, muscular, and perhaps vascular; (3) asthma associated with chronic bronchitis and emphysema; (4) asthma associated with nasal turgesence and sometimes with polypi and other mechanical obstructions, or with enlarged glands and other sources of irritation in the nose nasopharynx. While these divisions are not pathological divisions and are not coordinate, Dr. Cohen regarded them as useful working rules. In treatment asthma dependent upon vasomotor ataxia is to be prevented by constitutional measures, diet, hygiene, hydrotherapy, exercise, massage and the like, and the administration of such remedies as barium chloride, picrotoxin, ergot, atropine, suprarenal gland, strychnine and measures which raise vascular tone. Exciting causes are to be avoided. For the relief of paroxysms he suggested suprarenal spray or inhalation, or if necessary hypodermic injection. Narcotic asthma powders may be used, but not continued. Nauseant expectorants are useful in spasmodic asthma. The speaker gave the conditions in which choice should be made of the different agents.

Dr. G. Hudson Makuen reported a case of nasopharyngeal irritation as a cause of asthmatic breathing relieved by operation.

The Diagnosis of Major Hysteria.—Dr. Theodore Diller, of Pittsburg, in this paper emphasized the diagnostic importance of the condition, and said that among the failures to recognize it are the too limited conceptions of its manifestations, a too great insistence upon crying and laughing spells or convulsions as expressions of the affection; the failure to recognize that the symptoms may change little and persist for years, and that the disease may be

thoroughly chronic; the failure to recognize the disease is not rare in men and rather common in children, and the failure to recognize the great diagnostic value of sensory changes. A clear recognition of hysteria and a definite and positive statement to patient and friends that the disease is well understood constitutes the first step in treatment. Dr. Diller believed that in damage cases great injustice is done the sufferer from major hysteria by the jury, who regards it as a trifling matter or a species of fraud.

Dr. Mayer, of Pittsburg, agreed with the author when he said that hysteria is a mental disease akin to insanity, and believed that physicians are often prone to forget that the hysterical symptoms are due to a primary mental condition, that there is a congenital psychosis inherited in the individual.

Amnesia.—Dr. C. C. Hersman, of Pittsburg, in this paper reported the following clinical case: A man, aged forty, left his home in 1892 without cause. He thought he was going to the Atlantic Coast, but went to Cleveland. Returned in four days and wanted to start for his home in Austria. He was treated in a hospital for two weeks and at his home for three or four weeks. Complete recovery. In 1903 he left the city, not knowing where he went. Does not know where he first came to himself. He left Boston for Jamaica. He was under different names, which condition he thought was imperative. He felt as though he was undergoing a transformation, and that all his past was blotted out. A part of the time he thought he was dead and could not understand himself. He returned in six months, placed himself under treatment and again made a complete recovery.

Lax Sanitation—The Cost of It.—Dr. S. P. Heilman, of Heilman Dale, in this paper made a plea for a more united effort to secure legislation which shall prevent laxity in applying those sanitary precautions and safeguards to which the public is entitled. He quoted statistics showing the enormous loss to the States of New York and Pennsylvania by deaths from preventable diseases. Dr. Heilman came as a representative of the Society of the Associated Health Authorites and Sanitarians of Pennsylvania, and stated that at the last meeting two propositions were made: (1) That the Medical Society of the State of Pennsylvania should be asked, along with other societies, to unite with that Society in drafting a bill for the registration of vital statistics of the State, because upon that is based a true system for the exact determination of the health of the community; (2) that this Society shall lend its influence to the enactment of laws which shall provide for a county health officer, and a deputy township health officer, who shall be under the instruction and direction of the State Board of Health, to supervise sanitary affairs of every township, independent of any local influence.

(To be Continued.)

BOOK REVIEWS.

A System of Practical Surgery. By Prof. E. von Bergmann, M.D.; Prof. P. von Bruns, M.D., and Prof. J. von Mikulicz, M.D. Volume 3. Translated and Edited by William T. Bull, M.D., Professor of Surgery, College of Physicians and Surgeons, Columbia University, New York, and John B. Solley, M.D., New York Surgery of the Extremities. Lea Brothers & Company, New York and Philadelphia.

The third volume of this important work follows close on the heels of its predecessors, and fully equals, if it does not surpass, them in value and interest. The list of contributors includes men of the highest rank in the several branches of surgery to which they have devoted themselves, and the sections they have prepared for this magnificent system contain the very essence of their manifold experiences and labors. The present volume is devoted to the extremities, and the surgery of these regions is elaborated with the greatest possible attention to detail. The minutiæ of treatment are given with a fulness adapted to the needs of the least experienced, while the thoroughly modern nature of the methods advised, the pathological discussions and the wealth of statistical information make the volume of much interest and value to the operating surgeon. The sections on the shoulder and upper arm are by Schreiber and Hofmeister, those on the elbow and forearm by Wilms, while the wrist and hand are discussed by Friedrich. Hoffa's section on the hip and thigh is especially interesting, and contains a valuable discussion of the various methods for the treatment of congenital dislocation of the hip. Of the bloodless procedures, he prefers a combination of the Lorenz with the Mikulicz method, and in certain cases advises open operation, with reduction of the head into the enlarged old cavity. The knee and the leg have been allotted to Reichel, and the ankle and foot to Nasse and Borchardt.

The essentially practical nature of the work has been pointed out in the reviews of the previous volumes, and the frequency with which surgical conditions affecting the limbs come under the care of the practitioner makes this volume particularly valuable for every-day consultation. The regional plan of classification customary in Continental books has much to commend it, and in this instance it has been carried out so systematically as to make reference to any particular subject very easy.

The American editors have added many illustrations to those of the German original, and the interpolated notes serve to bring the text fully into harmony with cis-Atlantic practice.

Atlas und Grundriss der Lehre von der Augenoperation. Von Prof. Dr. O. Haab, in Zurich. J. F. Lehmann, München.

This is the third volume of the series by the same author comprising "The External Diseases of the Eye," "Ophthalmoscopy," and "Operations on the Eye."

The first two books are sufficiently well known, and the third is of equal excellence. The author writes as if the task were a congenial one. He is a teacher of rare gifts, and the descriptions of operations are vivid and clear to a degree. The directions are never stereotyped, but practical and of a simplicity of language to impress the memory. Many of the more modern procedures are described, some of which are not yet firmly established; others which are accessible here are of much interest, such as the introduction of iodoform into the anterior chamber, and an elaborate and authoritative chapter on the use of the large magnet. It is natural that one misses certain familiar operations. The book is not exhaustive, as Czermak's great book will be, if it is ever finished, but the failure to mention de Wecker's scissors in the treatment of secondary cataract would seem to be an oversight.

The illustrations need more than a passing comment. The work of the artist was well shown in "External Diseases," and here the same precision and excellence of technic is apparent, and the subject seems better adapted to realistic delineation than do the variable appearances of disease.

ORIGINAL ARTICLES.

THE EARLY PHYSICAL SIGNS OF PULMONARY TUBERCULOSIS.[1]

BY LAWRASON BROWN. M.D.,
OF SARANAC LAKE, N. Y.

WHEN discussing the early physical signs of pulmonary tuberculosis, there are several facts that should be kept in mind. In the first place, early physical signs do not necessarily mean that the disease is in an incipient stage, and in the second place it is still an open question how deep one can explore the lungs by percussion and auscultation. Many authorities hold that extensive changes can occur in the lung structure with few or no physical signs on auscultation or percussion.

It has, moreover, been frequently pointed out that no tubercle bacilli are found in the sputum until ulceration has taken place. I have found that as soon as ulceration occurs, or as soon as tubercle bacilli are found in the sputum, the chances for recovery are considerably lessened.[1] When tubercle bacilli occur in the sputum, the disease in one sense is no longer incipient. The term "incipient," in this paper, is applied to those cases with slight local and little or no constitutional involvement. It should be added that of these cases only those with a favorable prognosis are as a rule admitted to the Adirondack Cottage Sanitarium. In the 201 incipient cases discussed in this paper, tubercle bacilli occurred in the sputum of 71 (35 per cent.). One hundred and seven cases had a lesion on one side only and of these 34 (32 per cent.) had tubercle bacilli. Of the remaining 94 cases in which there were lesions on both sides, tubercle bacilli occurred in 37 (39 per cent.).

Every effort should be made to make the diagnosis before ulceration has begun, and in many cases the physical signs are of great help, but the fact should be emphasized that absence of physical signs is not conclusive proof that the lungs are normal. In many cases the diagnosis must depend upon the symptoms, and in cases with symptoms of pulmonary tuberculosis very slight changes from normal in the physical signs are of great importance. The "closed lesions" of the Germans are not rare, and the diagnosis must in many of these cases rest upon the symptoms and physical signs. In a recent case at the Adirondack Cottage Sanitarium, the patient had marked physical signs with a great quantity of sputum, yet Dr. Twichell examined twenty-six specimens on as many days before tubercle bacilli were found. They were then numerous until his death, which occurred in about three weeks. Considerable time may elapse after the onset before physical signs appear. In 192 incipient cases the time of onset was from three weeks to ten years before admission. In 111 cases (58 per cent.) the patient did not apply for admission during the first six months of his illness.

Method of Examination.—The relative value of the information obtained by the various methods employed in physical diagnosis is not fully appreciated, or at least stated by all observers. The classical method of making the examination, *i.e.*, by inspection, palpation, percussion, auscultation, mensuration and radioscopy, is often overemphasized in some details and in some cases receives too rigorous adherence. I am speaking in regard to incipient pulmonary tuberculosis only, where I have found the following method gave me on the whole the best results:

The patient should be stripped to the waist and covered with a chest cloth or blanket. He should stand, if possible, or if too weak, be seated on a revolving stool. Recently I have thought that I had obtained better results from percussion when a patient stood in a corner or near a wall, instead of in the middle of the room, on account of the reinforcement of the sound. The chest should be carefully inspected anteriorly, laterally, posteriorly and from above on quiet breathing. Palpation should next be practised, but quiet breathing only should be employed. Percussion should be made while the patient is breathing quietly. When one has finished auscultating the patient may be made to breathe deeply to determine, if necessary, whether limitation of movement is present on either side above or below. I rarely find this necessary in the cases I see, as quiet breathing usually gives me the information desired. Percussion, too, after a full breath can now be practised and the girth and index of the chest be determined, as well as the movement of the bases of the lungs by percussion and radioscopy.

INSPECTION.

The chest should be bared to the waist and the patient placed in a strong light, preferably falling diagonally across his chest. As the data obtained by inspection are closely connected with those based on mensuration, both will be discussed at this time.

General Conformity of Chest.—The general conformity of the chest in incipient pulmonary tuberculosis varies but little from the normal. A considerable number of cases have strikingly well-formed chests, better developed in many

[1] Read before the Laennec Society of the Johns Hopkins Hospital, May 25, 1904.

instances than the average healthy chest. In 83 out of 193 incipient cases the chest was well formed. In 48 cases it was not well formed; and in the remaining 62 cases some asymmetry or slight deformity was present, though the chest on the whole was fairly well formed. The chest index, the ratio of the anteroposterior diameter to the transverse diameter at the nipple level, may in health be stated to be about 75. In 157 incipient cases of pulmonary tuberculosis the index was 74, practically normal. The ratio of the length of the chest to the height in 540 males measured by Dr. Sargent at Harvard was 19.1. The same proportion in the Adirondack Cottage Sanitarium cases show 19.9, and this in spite of the fact that the heights in the latter are inclusive of shoes. The chest then in incipient pulmonary tuberculosis may be said to be longer than normal.

The Thoracic Perimeter.—The circumferences of the chest on forced inspiration and forced expiration should, it is said, be together at least equal to the height. As our cases have been measured in their shoes, 2.5 centimeters have been allowed for error in men and 3 centimeters in women. In 80 men the two circumferences exceeded the height in 44 cases (55 per cent.) and were less than the height in 36 cases (45 per cent.). In 95 women in 20 (21 per cent.) they exceeded the height, in 75 (79 per cent.) were less than the height. A striking difference between the male and female cases is seen in these figures. It suggests that the perimeter has been calculated only for the male. (In 175 cases the perimeter exceeded the height in 37 per cent., was less than the height in 63 per cent.) A number of immature chests, however, are included in these figures.

Angulus Ludovici.—The prominence of Louis' angle does not seem to be much reduced in incipient cases. The angle has not been measured by a goniometer, and its prominence may therefore be due in some cases to the pyriform exostoses of the second costal cartilages, to which Rothschild has called attention. This author thinks Louis' angle much reduced or obliterated in pulmonary tuberculosis.

The intercostal spaces vary little from normal in early cases. The intercostal angle, as measured by the eye, was normal in 33 out of 45 incipient cases and narrowed in 12.

Asymmetry.—In truly incipient pulmonary tuberculosis the chest shows little if any deformity. Before basing any conclusions on asymmetry of the chest, all previous possible causes of such deformity should be excluded; for example: occupation, pneumonia, pleurisy, etc. The earliest form of asymmetry is probably manifested by the prominence of one clavicle. Out of 169 incipient cases one clavicle was more prominent in 107 (63 per cent.) and equal in 62 (37 per cent.). Of 88 cases with a definite lesion on one side, in 45 the clavicle was prominent on the affected side, in nine prominent on the opposite side, and in 34 cases the clavicles were equal. In 156 out of 193 cases no flattening of the chest on one side was noted on inspection. In 100 cases with a lesion on one side only 19 showed some flattening, in part at least, due to atrophy of pectoral muscle, which in 12 agreed with the lesion, and in seven occurred on the opposite side. The figures would seem to indicate that the right side is normally more prominent than the left. (In 11 "right-sided lesions" with asymmetry, depression occurred on the right in five, on the left in six. In eight "left-sided lesions" seven occurred on left, one on right.)

In 95 incipient cases with a lesion on one side the diameter from the nipple to the vertebral spine on the same level was noted. This showed that in 30 cases the affected side had a smaller diameter; in 34 cases the diameters were equal, and in 31 cases the diameter was less on the unaffected side. The figures, however, seem to indicate that the right diameter is normally larger than the left, but the diameters are somewhat affected by the lesions. [In 53 cases with a lesion on the right side, the right diameter was smaller in 12 cases (23 per cent.), larger in 26 cases (49 per cent.), equal in 15 cases (28 per cent.) In 42 cases with a lesion on the left side, the left diameter was smaller in 18 cases (43 per cent.), larger in five (12 per cent.), and equal in 19 (45 per cent.)].

In 193 cases there was one case with a funnel chest, one pigeon-breasted and one phthinoid. In five cases the sternum was prominent, in ten depressed, and in one prominent above and depressed below.

Scoliosis.—Slight scoliosis was noted in 22 out of 103 cases. The convexity was to the right in twelve cases (six with a lesion on right side, six on left); in ten it was to the left (eight with a lesion on the right side and two on the left).

Varices.—Attention has been called to the occurrence of varices on the affected side. They are frequently to be noted, but do not seem to me in early cases to occur sufficiently often on one side to warrant any conclusions.

Difference in Size of Pupils.—In 181 incipient cases, 15 had a difference in the size of the pupils. Of eight cases with a lesion on one side only, six showed an enlargement of the pupil on the affected side, two on the unaffected side. Of the seven cases with both sides affected, in three the pupil was larger on the side with the more trouble, in two the pupil was larger on the less affected side, and in two both sides were equally affected, but the right pupil was larger than the left. In the fifteen cases the right pupil was larger in twelve, the left in three (one had the lesion on the left, one on right, one on both—more on right). Little information can be obtained from the difference in size of the pupils in early cases of pulmonary tuberculosis.

Larynx.—In five cases out of 197 examined, one vocal cord moved less than the other. In two cases the limitation of movement was on the

affected side, in three on the opposite. This was the only abnormality noted in the laryngeal examination in these cases, which, however, presented no laryngeal symptoms.

Movement of the Chest.—In 101 cases with a lesion on one side, the movement by inspection and palpation was restricted on the affected side in 53, on the opposite side in 24; on both sides equally in two and was equal in 21. In one case the movement on the affected side was greater but the side lagged. I have thought it would be of interest to compare the movement of the two sides, as obtained by inspection, percussion of the bases and radioscopy of the diaphragm. Twenty-two cases have been examined. In three cases inspection showed the movement equal. In 15 the movement was restricted, on the affected side in 10, on the unaffected in five. Four cases had lesions on both sides. Of the 10 cases with the movement noted by inspection as limited on the affected side, in five percussion of the bases and radioscopy of the diaphragm coincided. In eight cases of these 10 inspection and percussion showed limitations of movement on the affected side.

In seven cases radioscopy agreed with inspection. In five cases inspection showed the movement restricted on the unaffected side. In one case percussion and radioscopy coincided with it. In two of these five cases percussion and X-ray showed a restriction of movement on the affected side. In one case percussion showed no difference, while X-ray showed a limitation on the affected side. In the remaining case X-ray showed a limitation on the affected side, percussion on the unaffected side. Inspection showed no difference in movement in three cases, in two of which both percussion and X-ray indicated a limitation of movement on the affected side. The remaining case had a limitation of movement on the affected side by percussion, on the unaffected side by X-ray. From these figures it is seen that inspection showed a limitation of movement on the affected side in 55 per cent., percussion in 72 per cent. and radioscopy in 72 per cent.

For some time past I have had my attention called to the fact that when the movement was restricted at the apex it was often exaggerated at the base. This is easily made out by inspection and palpation. When the movement is equal, or nearly so, I always carefully examine the bases to see if I get more movement on the affected side. In 12 incipient cases with a lesion on one apex, I noted in nine that the movement, while restricted at the affected apex, was exaggerated at the base. In three cases the site was doubtful, but the phenomenon occurred on the side supposed to be unaffected. It was noted in five cases with lesions on both sides. I would like, however, to call attention to the fact that in all these 17 cases, the phenomenon occurred upon the right side. I have observed the same phenomenon in many advanced cases.

I regret that I have not recorded separately the relative movement of the two shoulders and would add that the observations of movement were made over the infra-clavicular fossæ and over the infra-axillary regions.

Spirometry has not yielded information of sufficient value in early pulmonary tuberculosis to encourage us to make a study of it. I cannot but believe that in some cases it may be decidedly dangerous.

PALPATION.

Palpation has seemed to me to be of little value in these cases, except as an aid in determining limitation of movement. Increased normally on the right side it is difficult to detect a slight increase of the vocal fremitus if the lesion is at the right apex. When the lesion is at the left apex the vocal fremitus may be of more value. If it is equal on both sides it is probably increased on the left. In 94 cases with a lesion on one side the palpation was normal in 64, greater on the affected side in 23, and on the unaffected in seven (six on the left side).

PERCUSSION.

In many early cases little or no information can be gained by percussion as ordinarily practised. The note is unchanged and the same on both sides. When the involvement of pulmonary tissue necessary to produce any change in the percussion note is considered the absence of dulness in the incipient stage is not to be wondered at. Cornet[2] has stated that in general to produce any change in the percussion the area of disease must have reached an extent of four to six square centimeters and a depth of two centimeters. Alison[3] held that the air capacity of the lung must be reduced one-third to produce any change in the percussion note, and one-half to produce dulness. This would explain why a small lesion can be more easily detected by percussion at the apex than elsewhere. The note obtained on percussion can in many cases be analyzed in regard to loudness, duration and pitch. In some cases the first change to be noted is a shortening of the duration, though in many cases it is already accompanied by a rise in the pitch and a diminution of the loudness. Occasionally emphysematous changes occur which mask the dulness, and even in some quite advanced cases little or no dulness can be obtained. This change is no doubt the cause of the relative slight dulness at times detected on the apparently unaffected side.

With a bared chest the patient should stand in a corner or near a wall with his arms hanging loosely by his sides and his head straight. I have found it best to begin with immediate percussion of the clavicle. Care should be taken to strike the clavicles at the same distance from the extremities and at the same angle relatively to a horizontal plane, otherwise a slight difference in note may mislead one. The remainder of the two sides is then compared and often when per-

cussing one side I find it well to go from the resonant parts below to the suspected apex.

I have recently thought that by standing behind the patient, who faces a wall, and percussing the apex I could get better results. To be more explicit, I place the palm of my hand over the suprascapular area and bend my middle finger until it lies firmly against the skin in the supraclavicular fossa. By this procedure one, so to speak, grasps the apex of the lung. Percussion is made on the distal phalangeal joint. Whether it will prove of value to others I cannot say, but it enables me to get the plessimeter finger into more nearly the same position on both sides and allows the finger to lie closely upon the part to be percussed. When examining the back I find it always of value to make the patient cross his arms, putting his hands on his opposite shoulders and bringing his elbows together. His muscles should be relaxed, his shoulders dropped and his body bent slightly forward. This is practically one of the positions recommended by Dr. Corson in 1859.

In many cases on careful percussion a slight change in note is detected at the level of the second rib. If we percuss from below upwards, at this level, the note becomes slightly higher in pitch and possibly a little shorter. I have not found this to be pathological, but have attributed it to the increased thickness of the pectorals in these areas.

The note at the right apex, especially just below the clavicle, is said to be slightly higher in pitch than that at the left. I have found this in a few cases, but in these it caused no confusion. It is well, however, to begin percussion on the left side. In left-handed patients this relative dulness is usually reversed.

In 28 cases out of 201 percussion was negative, while auscultation revealed some abnormal signs.

In 107 cases with a lesion on one side, 25 cases were normal on percussion; five exhibited slight dulness on the opposite side; and in one case the note at both apices was hyperresonant. In the remaining 76 cases the change in the percussion note occurred at the apex in 73, 37 in front, 12 behind and 24 both in front and behind. In 12 cases the change occurred only above the clavicle.

In 16 cases there were slight differences on percussion without any accompanying auscultatory signs. In three cases there were no abnormal physical signs on auscultation. In the remaining 13, auscultation revealed some change on the opposite side.

In 1889 Krönig[4] published in the *Berliner klinische Wochenschrift* a description of a new method of percussing the apices. The height of the apices above the shoulder girdle has often been discussed, and I believe that it is not generally agreed that they always rise to the same level. Krönig has applied to the apex the same method of percussion and the inductions from it that we ordinarily apply to the heart. A slight change of the position of the cardiac dulness does not mean to us what a change in the area does. Krönig marks out the part of the lung lying above the clavicle and scapula on each side and compares the size of the resonant areas. A slight change in position does not necessarily imply disease, but a contraction, a shrinking of the area of resonance on one side is very suggestive. To map out this area very light percussion should as a rule be used. When the disease becomes arrested early, vicarious emphysema has been stated to obliterate any change that had existed in this area. The supraclavicular fossa, if closely observed, is at times seen to retract during inspiration, but usually only in advanced cases. In early cases, as Senator points out, the apex of the lung usually rises slightly (about one-quarter inch) as shown by percussion. Lack of sharp definition in this area of resonance on the affected side is also a point of value.

Auld's[5] method for percussion of the resonant area above the clavicle will never, I believe, come into general use and lacks the direct simplicity of Krönig's.

Percussion I have found to be of value in determining the movement of the bases of the lungs. It has given me better results than Litten's sign, possibly because I am insufficiently practised in the latter method. I instruct the patient while standing to put his hand on the back of his neck and to raise his upper arm until it is perpendicular or as nearly so as he can make it. I explain to him what I am about to do and then determine the lower limits of the lungs in the anterior or midaxillary line on deep inspiration and full expiration. The amount of movement may increase after several deep breaths. To determine the value of this procedure I have examined 41 cases in this manner and compared the movement with that of the diaphragm as determined by radioscopy. In three cases the location of the disease was questioned and in six a lesion existed on both sides. Deducting these we have 32 cases in which the lesion was on one side only. Of these 32 cases, in 20 the movement was shown to be limited on the same side both by percussion and X-ray. In 17 cases the limitation was on the side supposed to be affected and corresponded with the other physical findings. In three cases the limitation was on the side presumably unaffected. One of these cases had marked scoliosis with the concavity on the left side, which was apparently normal but had restricted movement. The second case had only a slight pleurisy at the left infra-axillary region. The third case was that of a medical student with the lesion at the right base and possibly the left.

In 12 cases the findings by radioscopy and percussion differed. Of these the movement on percussion was equal in two, while the X-ray showed marked limitation on the affected side. In two cases the lower limits on the left could not be satisfactorily determined on account of the stomach tympany, while the X-ray showed the

diaphragmatic movement limited on the affected side. In two cases the X-ray showed the movement to be practically equal (one-fourth centimeter difference), while percussion showed the movement limited on the affected side. In one case the movement was practically equal by both X-ray and percussion (one-fourth centimeter less movement on the affected side by percussion). The breast obscured the diaphragmatic movement in one case, which percussion showed to be limited on the affected side. In the remaining four cases the results obtained by percussion were correct in two and wrong in two, in which latter the X-ray was right in regard to the side affected.

Twenty-two of these cases were incipient. Four have to be excluded, as the location of the disease was not determined in one and disease occurred on both sides in three. Of the remaining 18 cases both percussion and X-ray showed in one case a limitation of movement on the apparently normal side. In 14 cases (82 per cent.) percussion showed a limitation of movement on the affected side. In the remaining three cases percussion showed equal movement in two, both of which seemed to be deep-seated lesions. The X-ray showed limitations of movement on the affected side in all three of these cases, but failed to show it on the suspected side in four cases in which percussion demonstrated it.

From the little experience I have had with this method of determining the relative movement of the diaphragm on the two sides by percussion, I am led to believe it may prove of considerable value as one of the links in the diagnostic chain in early pulmonary tuberculosis. In cases with central lesions I think it is less useful, and in these radioscopy still seems to be our most valuable aid. How soon after meals a patient should be examined is also a point to be settled, as I can conceive that a large meal might retard the movement of the diaphragm on the left, possibly on both sides.

The X-ray examinations were made with the patient standing about 18 inches from the tube, which was on a level with the fourth costal cartilages.

A cracked pot note is occasionally obtained in incipient cases (in one out of 201), due to the elasticity of the chest. It usually occurs in the subclavicular fossa.

I have not noted in any of these incipient cases any increase of resistance to the plessimeter finger. Auscultatory percussion is not, as far as I am aware, of any assistance in very early cases. My attention has recently been called to the "Tastpercussion" of Ebstein,[6] but I have not had an opportunity to put it to the test in any of these cases.

AUSCULTATION.

There is a great temptation when dealing with incipient pulmonary tuberculosis to begin the examination with auscultation, as it undoubtedly yields the earliest and most trustworthy information. Inasmuch as the disease begins most often at the apices it is well to commence each manoeuver at one of these points.. The whole chest should be gone over with the stethoscope on quiet breathing. I find it then convenient to examine the vocal resonance, paying especial attention to the whispered voice sounds. The chest should then be examined during a full inspiration after coughing. It is often necessary to explain to the patient how to cough and how to breath to bring out well any adventitious sounds.

The differences between the two sides of the chest on auscultation have been mentioned so often that it is only necessary in this paper to recall the fact to dismiss it. It should be noted, however, that while most observers hold that the excess of natural breathing occurs on the right side, Alison,[3] from observation on about 100 boys, girls and young females, found it increased on the left in 10 and equal in the others.

The first change to be detected on auscultation, and in fact the very first abnormal physical sign in pulmonary tuberculosis, relates to the vesicular murmur. Changes may occur in the quality of this murmur, in the relative duration of its two parts (inspiration and expiration) or in its continuity and equality. The first change to be detected is often some harshness and increased loudness of the vesicular murmur. This in most cases is an increase of loudness or elevation of the expiratory murmur,—prolonged, high-pitched expiration. Grancher[6] held that the earliest change is a low, rough inspiratory murmur, which if sharply defined at one apex is very significant. Wavy breathing precedes weakened breathing, which probably occurs only when the area of infiltration has reached some size.

Vesicular Murmur.—A change in the vesicular murmur is often the only variation from normal found on auscultation. In many cases the vesicular murmur on quiet breathing is very distant or weak. However, this may be due to an improper manner of breathing and not to pathological changes. The patient should be directed to take a full deep breath and the chest should be auscultated with the naked ear as well as with the stethoscope. A series of short, quick inspirations often aid in the examination. When loss of vesicular murmur is detected at both apices the patient should be made to breathe noiselessly through his mouth. This in some cases will enable a good vesicular murmur to be heard. Some deficiency in vesicular murmur was noted in 82 cases. Of 107 cases with a lesion on one side, 39 had some loss of vesicular murmur; of 94 with a lesion on both sides in 43 there was some deficiency in vesicular murmur.

Prolongation of Expiration.—The first change to be detected by auscultation in some cases is a prolongation of the expiration, often slightly raised in pitch. In 107 incipient cases with a lesion on one side the breathing was normal in 26. In the remaining 81 cases prolonged ex-

piration was present in 29, being the only auscultatory sign in six. When lesions occurred on both sides (94 cases) prolonged expiration was present on one side in 29 cases, on both in eight.

Wavy Breathing.—Dr. Jackson[7] in 1833 first called attention to the fact that in some pulmonary diseases the vesicular murmur is not continuous, but, as Dr. Thompson[3] has called it, "wavy," an adjective since widely used to designate this change in the vesicular murmur. In some pronounced cases the breathing is not heard for a time, only to reappear and disappear several times in a single respiratory act. This has been termed cog-wheel or jerky breathing. The wavy quality occurs chiefly during inspiration, but at times may be heard in expiration. Wavy or cog-wheel breathing has not occurred often in our early cases, where the lesion is situated at the apex. Wavy breathing may be due to the forced inspirations and heard only when such are taken. Under these circumstances it has no significance. When confined to one apex, however, it is very suggestive, and a patient with it should always be looked upon with suspicion. Wavy breathing over both sides is quite frequent in nervous patients and is no indication of disease. I have frequently noted it at the base behind, especially on the left side. It was present in nine of the 201 cases, seven on the left, two on the right. In three of these cases a lesion developed later at the site of the wavy breathing.

In many cases, however, no further change has ever taken place, and the "wavy breathing" was in some cases undoubtedly a cardiorespiratory murmur. One case in particular led me astray some two years ago. A young woman, extremely nervous, was sent to Saranac Lake by her cousin, a physician. Her sister had died of pulmonary tuberculosis two or three years previously. She had few symptoms of pulmonary tuberculosis other than those attributable to her nervous condition. On the physical examination it was noted that she had marked exophthalmos, some general enlargement of the thyroid gland and a slight tremor. However, "thinking in tuberculosis," as we have been accused of doing, a marked cog-wheel respiration at the left base led me to believe she had some pulmonary trouble. Dr. Osler fortunately saw the patient and set us—I had some backing in the error—right. She had a cardiorespiratory murmur, six to the respiration, and is now well, married and happy in her "recovery" from pulmonary tuberculosis.

In 201 incipient cases wavy breathing was present at the site of the lesion in 23. In 107 of these cases with a lesion on one side wavy breathing was localized at the site of the lesion in 10. In 94 cases with a lesion on both sides, wavy breathing was present in 13 cases, usually on the less affected side (eight out of 13).

Weakened Breathing.—Weakened or distant breathing at one apex is often a very suggestive sign. It was present in 10 of our cases with a single lesion; in one it was the only abnormal auscultatory sign, and in six the only change to be detected on examination of the respiratory murmur. In 94 cases with a lesion on both sides, the breathing was distant in 10. The weakened breathing in these cases was at the site of the lesion or lesions.

Puerile and Harsh Breathing.—Puerile and harsh breathing have also been rather infrequent in our early cases. I have found puerile breathing frequently on the unaffected side in advanced cases and have come to look upon it as by no means an unfavorable sign. In a small number of incipient cases (four) harsh breathing has accompanied prolonged expiration. In 107 cases with a lesion on one side harsh breathing with some loss of vesicular murmur was present in six; puerile breathing in six. Of 94 cases with a lesion on both sides, harsh or puerile breathing was present in 28 cases. The vesicular murmur was normal in 18 of these, *i.e.* the breathing was puerile.

Vocal Resonance.—The vocal resonance often varies directly with the vocal fremitus, and like the latter is more pronounced on the right. A slight increase on the right is therefore difficult to detect. In 201 incipient cases the vocal resonance was noted as normal, *i.e.*, slightly increased on the right, in 124. In 77 cases it was increased and corresponded with the lesion in every case but one.

Râles.—It is rare in my experience to detect on quiet breathing any adventitious sounds in the lungs in incipient pulmonary tuberculosis. When râles are detected on quiet breathing I usually assume that the case is no longer in the incipient stage, and generally find my assumption to be correct on further examination. Fraenkel,[8] indeed, holds that when any râles are heard the disease is no longer in its incipiency. Râles are in most incipient cases heard only during forced inspiration following cough. They may be moist or dry. Fine and medium moist râles are the two varieties most frequently heard, although occasionally a few sonorous rhonchi may be almost the only physical sign detected.

Quite often a few râles, fine or moderately coarse, are heard after coughing in the infra-axillary region. They may persist for some months after all symptoms have disappeared, and I am not inclined to attach too much importance to them after the diagnosis has been made. Râles in the infra-axillary region were heard in 12 out of 201 incipient cases. In eight of these cases, who have been discharged, the râles had disappeared.

I have occasionally heard a few coarse, moist râles at one apex.

In 107 incipient cases with a lesion on one side the only abnormal physical sign detected in 18 cases were some râles, fine in 13 cases and moist in five. In 48 of the remaining cases râles with other physical signs were present. In two cases the only râles noted were a few rhonchi at the apex-posterior in one, and at the infra-axillary

region in the other. The following figures may enable you to get some idea of the relative frequency with which various kinds of râles have been noted. In 107 cases fine râles occurred in 43, moderately coarse in eight, coarse in one, rhonchi in two, mixed râles in 12. In 94 cases in which there was a lesion on both sides, râles occurred on one side only in 35, on both sides in 39, and in 20 no râles were detected. The relative frequency of the various râles was as follows: Fine, 40 cases; moderately coarse, four; rhonchi, one; mixed, 29.

So in 201 cases, râles were detected in 140.

Muscle Sounds.—Muscle sounds produced in deep inspiration are more frequently heard in the infra-axillary region, though they may occur at the apex behind or at the infraclavicular fossa. These sounds should be kept in mind and investigated in the deep inspiration following cough. Râles in many cases become coarser on coughing and can then be differentiated. But if the sounds occur only during the deep inspiration following cough, a correct diagnosis is more difficult. I well remember the first marked case I saw about four years ago. I thought the patient had fine râles over the entire back on the right, but later discovered that the râles were only muscle sounds.

Pleurisy.—Pleuritic friction has been of rare occurrence in our early cases, possibly because of the apical location. It was noted in only two of the 201 cases. I might say that I have often been impressed with how seldom one hears a friction rub in pulmonary tuberculosis. Even when a patient is suffering from acute pleurisy often no pleuritic friction can be made out for some time.

In regard to the local signs occurring after the tuberculin reaction in incipient cases, they are often conspicuously absent. In some cases I have noticed a few fine râles or a slight loss of vesicular murmur not detected either before or after the reaction.

A systolic murmur occurs below the clavicle more frequently in advanced than in incipient cases. I have heard it occasionally in some of our incipient cases, but it seems to be of slight importance. The heart sounds were transmitted more widely than normal over the chest in two cases.

From the consideration of these cases it is seen that the most common picture obtained by percussion and auscultation is slight dulness above the clavicle with some deficiency of vesicular murmur with or without prolonged expiration, and a few râles, usually fine, during inspiraton following cough.

Site of the Primary Lesions.—In 29 of the 201 cases which have been studied in this paper, it was impossible to determine the starting point, but in 172 cases after much deliberation the first point of attack, as indicated by the physical signs, has in all probability been determined. Of these 172 cases, in 105 the disease started on the right side, in 67 on the left. Of the 105 cases starting on the right side, 102 commenced at the apex, three at the base. Of the 102 cases with an apical origin the abnormal physical signs first appeared anteriorly in 56, posteriorly in 21. Twenty-eight cases began in the supraclavicular, five in the subclavicular fossa. The cases that started on the left side showed practically the same points of origin. In 36 cases it was impossible to decide whether the disease started above or below the clavicle.

CONCLUSIONS.

1. Absence of physical signs in the chest is no better proof that a patient has not pulmonary tuberculosis than absence of tubercle bacilli in the sputum.

2. Tubercle bacilli occurred in the sputum of only 71 (35 per cent.) of 201 incipient cases.

3. Fifty-eight per cent. of these cases did not apply for admission into the Sanitarium within the first six months of illness.

4. Auscultation is by far the most important method of physical exploration in incipient pulmonary tuberculosis. Inspection (including mensuration) and percussion seem to me of nearly equal importance. Palpation is of less value.

5. Auscultation should be practised before the patient is made to breathe deeply, as otherwise fine crepitation may be overlooked.

6. In many incipient cases little or no deformity of the chest exists. In a majority of the cases the chest is well developed, though possibly a trifle long, with a slight prominence of the clavicle on the affected side.

7. The intercostal spaces and angle as well as Louis' angle are in the majority of cases normal.

8. The movement of the chest as noted by inspection is in the majority of cases restricted on the affected side. Restriction of movement on the unaffected side is by no means uncommon.

9. Careful inspection showed a restriction of movement in 10 out of 18 cases, percussion of the bases revealed it in 13, radioscopy in 13.

10. The lower part of the affected side shows in some cases an exaggerated movement on inspection, which may be of value in certain cases.

11. The vocal fremitus was normal in two-thirds of the cases and was three times more apt to be increased on the affected than on the unaffected side.

12. Direct percussion upon the clavicle has not proved of much value in these cases.

13. Some degree of dulness may occur without change in the auscultatory signs.

14. Krönig's method of percussion is of value in the examination of incipient cases.

15. Percussion and radioscopy seem of nearly equal value in determining the movement of the base of the lung. Radioscopy has a distinct advantage in deep-seated lesions; percussion, possibly, in "pleuritic" cases.

16. In 28 out of 201 cases (13.9 per cent.) percussion was negative, while auscultation revealed some pathological signs.

17. Prolonged expiration was present in 32 per cent. (in four per cent. as the only abnormal auscultatory sign).

18. Wavy breathing was present at the site of the lesion in 11 per cent. "Wavy breathing" at the left base may be a cardiorespiratory murmur.

19. Weakened breathing at the site of the lesion was present in 10 per cent. (in one per cent. as the only abnormal auscultatory sign).

20. Puerile breathing was present in 12 per cent., harsh breathing with loss of vesicular murmur in eight per cent.

21. Some deficiency in the vesicular murmur was present in 41 per cent.

22. The vocal resonance was normal in 62 per cent., increased at the site of the lesion in 38 per cent.

23. Râles occurred in 70 per cent. The following order indicates their relative frequency: Fine, medium moist, rhonchi, mixed.

24. Pleuritic friction occurred in but two cases (one per cent.).

25. In these 201 cases the site of the primary lesion was most frequently above the clavicle, then in the suprascapular area and subclavicular fossa. Sixty-one per cent. occurred on the right side.

ARE THE INSANE RESPONSIBLE FOR CRIMINAL ACTS?[1]

BY JOHN PUNTON, M.D.,
OF KANSAS CITY, MO.

THE prevalent use of insanity as a shield for crime, renders its medicolegal study of more than passing interest. In view, therefore, of its extreme importance and practical significance, it is somewhat surprising to find the scant attention which it has received in the published transactions of this worthy organization. Moreover, the contributions which have appeared, together with their discussions, have met with no definite mutual agreement, thus leaving the novice in psychiatry to grapple with this momentous question largely unaided by those whose experience and competence enables them to speak with authority.

As one of the younger accessions to your ranks, I trust it will therefore not be construed as presuming on my part to thus attempt to deal with a subject of such acknowledged perplexity, for my purpose is not to assume the rôle of a disgruntled critic, but rather the attitude of an interested student of practical psychiatry, inquiring after truth of those whose opportunities for clinical research and ripened experience qualifies them to impart reliable information and instruction concerning the question at issue.

Whether justified or not, it is my belief that much of the confusion which now prevails relative to medicolegal matters in courts of law, is largely due to the apparent indifference manifested by such specialized organizations as this, to furnish the general medical profession with definite specific knowledge concerning the abstruse problems of which they alone are the only recognized capable exponents. Hence, in every community where insanity becomes a plea for crime, and the question of mental responsibility is referred to the local medical profession, it is very distressing to find the wide difference of opinion that prevails between apparently equally competent medical witnesses, relative to its validity. If, however, this association has any function distinctly its own, it would seem to be the right to decide whether the insane are mentally responsible for criminal acts, and if so, what adequate disposition should be made of them, in order to meet the ends of justice.

That medical men are not agreed at the present time in reference to this matter, is very clear, but it is certainly highly desirable that a consensus of opinion be attained by no less authority than this able body of competent alienists, as to the mental conditions which ought to exonerate a criminal from punishment. In this connection, we are reminded by Judge Emery, of the Supreme Court of Maine, that the science of medicine is the oldest of sciences, that it has attracted to its ranks the best intellects of every age, that its disciples have been distinguished for their zeal, ability and untiring labor, and that in the thousand years of its existence it must have elucidated and established a vast number of truths, which its devotees should be able to state clearly, impartially and accurately in courts of law. Why, then, he asks, do our courts find medical evidence so often unsatisfactory? Lawyers, he claims, understand that medicine is not an exact science, and that the causes and course of disease of both body and mind are hidden from inspection, and often can be only surmised, but these allowances do not, to the lawyer's mind, account for all the faults of medical testimony.

The courts, according to this eminent authority, desire to know, not so much individual, as the consensus of opinion of the entire medical profession. It is assumed by the courts that in the present state of medical science, the medical profession has accepted certain conclusions as correct. Many new theories may be started, and numerous modes of treatment suggested by the few, while the great body of the medical profession refuse to sanction or adopt them. The

[1] Read before the American Psychological Association, St. Louis, Mo., June, 1904.

consensus of medical opinion is, however, what the courts desire, and not individual opinion.

Now, applying this principle to the subject of my theme, I presume no one here will deny the proposition, advanced some time ago by Dr. Mercier,[1] the noted English alienist, viz., "that very few, indeed, of the insane are wholly irresponsible," by which, he says, he means that there are very few indeed of the insane who ought never to be punished for wrongdoing or, to put it as he states, with brutal plainness, "it is, in many cases, right and just to punish an insane person for wrongdoing." This, I admit, is contrary to common belief and legal opinion, for there is a very prevalent notion abroad, which gets expressed from time to time in sentimental expressions of horror and disgust at the very idea of ever punishing an insane man, under any circumstances, or for any act of wrongdoing. It is, however, this universal belief in immunity of punishment, that constitutes the foundation for the plea of irresponsibility for crime, on the ground of insanity.

That total and complete irresponsibility of the insane is the magnetic watchword that insures good care and kind treatment to those unfortunates confined in our State and private insane hospitals, is undoubtedly true, and the theory in itself is a most excellent one when used in its proper sphere, or strict relation, for, as Dr. Wherry[2] aptly states: "It alone has aroused the sympathy of all God's people, for this most unfortunate class, it alone has broken the shackles from a thousand maniacs chained in dungeon cells, it alone has reached out its charitable hand and protected the wards of the State, beside ringing the death-knell of brutality in hospitals for the insane, and giving us kindness, gentleness and brotherly love instead."

Admitting all this, yea, even more; it is nevertheless, according to the writer, a false doctrine, and cannot in fact be substantiated by practical clinical experience with the insane. For the good it has already done, and is still doing, it is well to allow its influence to reign supreme in hospitals for the insane, but it should never be held in courts of law, as the true and correct criterion or standard for justice, in all cases of insanity, as it is contrary to all the facts and evidence furnished by practical clinical psychiatry.

It is at this point, however, where law and medicine come in conflict, both by authority and teaching, for the majesty of the law, as it now stands, declares that no insane person is responsible for his acts, indeed, in a strictly legal sense, there is no such thing as an insane criminal. Concede the insanity of the accused, and he is at once placed outside the ban of law, and not under its punishment. This theory of total and complete irresponsibility of the insane, therefore, corresponds to that form recognized by lawyers as legal insanity, in contradistinction to medical insanity.

The fallacy of this view, however, was ably set forth by Dr. Bancroft[3] in his essay on "Legal and Medical Insanity," which he read to this association in the year 1900. In this he clearly demonstrates how imperfectly insanity is understood by the lawyer as well as the general medical practitioner, and emphasizes the need of a definite consensus of opinion by those most competent to judge relative to its misleading character, both for its educational as well as humanitarian purpose.

To the legal mind, any act in the insane, which in the sane would be criminal, lacks every element of crime. The act is impelled, from this standpoint, by an insane impulse or delusion, which cannot be resisted or controlled; hence it is not the result of any criminal intent. A sane man, however, who has committed a crime, may become insane either before or after conviction for the crime, but the moment this occurs, he is no longer a criminal, but an insane man, and thus free from legal punishment. It would seem, therefore, that Dr. Mercier's claim, viz., that the insane should be punished for wrongdoing, is an open violation of the common law of both England and America. He, however, qualifies this statement by adding that "No insane person ought, for any act, to be punished with the same severity as a sane person ought to be punished for the same act," and he also says "that every institution for the insane is conducted in accordance with this great principle."

That insanity carries with it a certain immunity from punishment all will agree, and there are good sound scientific reasons why this is true, but every alienist of wide experience recognizes that there are degrees of responsibility associated with insanity, and that the majority of the insane should be held responsible for many of their misdeeds, and consequently incur some form of penalty or punishment. That this is the actual consensus of medical opinion by those most competent to judge, is clear, for the principle of petty punishment is practised in every hospital for the insane of my acquaintance. Every medical officer of our State and private insane hospitals realizes that many of the patients in his institution often commit misdemeanors deliberately, wilfully, and with malice aforethought, beside knowing right from wrong, and with full understanding of the nature, character, and even consequences of their misdeed. Hence, we find the insane subject to mild forms of punishment, according to the nature of their offence, such as not allowing them to attend the weekly dance, on account of fighting, or refusing the privilege of their parole, after an attempt to elope, or if caught pilfering, cutting off the weekly allowance of tobacco, or if abusive to the medical officer, removal from a convalescent to a more disturbed ward.

These and many other similar penalties are imposed upon the inmates in every well-managed

institution, not simply to maintain discipline, but also as a penalty for misconduct, and while the term "punishment" may be objected to, as having the sound of harshness, yet whether these inflictions be considered merely the withdrawal of certain privileges, or as precautionary measures, and not true punishments, in order that this ruling may be valid, the penalties imposed must be permanently enforced. As a matter of fact, however, the withdrawal of the privilege is not permanent, but only temporary, and subject to the same construction as that which applies to the sane man when he is sent to prison. There are, therefore, simply differences of degree and not of kind, and consequently equivalent to mild or severe forms of punishment.

In order to prove that the insane possess powerful control over their conduct, Dr. Mercier mentions the fact that in those patients whom he allowed "pocket money" the prospect of having this stopped restrained them from practises of mischievousness, destruction and other evil habits. Under no circumstances, however, we are informed, has the superintendent of a hospital the lawful right to punish in any way an insane person, because legally such persons are not responsible. It is surprising, however, in many criminal cases where insanity is used as a plea to exonerate crime, how the various members of the medical profession, as well as the public, insist upon punishment as being the only remedy for justice, even when the evidence favors the view of undoubted insanity of the accused. The same spirit incited the late Dr. Hammond, when placed on the witness stand in the celebrated trial of Guiteau, who assassinated President Garfield. When asked for his professional opinion, Dr. Hammond is said to have exclaimed, "He is insane, but hang him." According to law, we are told that under no circumstances have we the lawful right to punish an insane person, yet Guiteau was hung.

Not long since, in the city where I reside, there occurred two atrocious murders. In both, the plea of insanity was urged as a defence for the crime. In one it was proven that the prisoner, a young married man, was an epileptic, having had characteristic periodic attacks since childhood, up to the time of the murder. The crime was a most brutal one, and associated with all the damnable elements which are peculiar to epileptic homicidal mania. Upon being called to examine the prisoner by the defence, and having had him under observation during his confinement in the jail, I did not hesitate to pronounce him insane, the epilepsy being accompanied with pronounced religious delusions. The marked difference of opinion, however, that prevailed between the medical men, and the high state of public prejudice against the accused, as well as the result of the trial, which ended in the man paying the death penalty on the gallows, is the responsible cause of my appearing before you to-day, as it at once created a desire to be set right, if my views were not in keeping with modern medical thought and practical clinical psychiatry.

In order that you may further understand my purpose, the following brief editorial, taken from one of our daily papers, speaks for itself:

Taylor Case Verdict.—"The attorneys for Bud Taylor have the satisfaction of knowing that they did all they could to save their client from the consequences of his crime, and the public has the satisfaction of knowing that the deliberate ambushing and slaying of a young woman of the community without just cause or provocation, is to meet the punishment it deserves—if the verdict of the criminal court shall stand. The defense made out a strong case from its viewpoint. Epilepsy as an excuse for murder saved one man from the gallows a couple of years ago in this city, but it was unsuccessfully evoked in the present case. Only one man of the twelve voted for insanity, and his convictions were not very pronounced.

In some respects the trial was one of the most remarkable in the criminal history of Jackson County. Not the least interesting feature of the proceedings was the unusual array of medical experts put upon the stand on both sides, and the wide divergence of their opinions. At times this divergence bordered on the humorous, if the matter under consideration had not been of so serious a character. How eminent physicians, graduates of the same school of medicine, could arrive at two entirely opposite conclusions from the same given set of facts is one of those strange things with which this world abounds. If books and clinics and observation and experience, the sum total of knowledge used by the physician in practising his profession, teach anything, they should teach substantially the same thing all the time. Making due allowance for the difference in personality, temperament, physical condition and all that, the effect of the same cause must generally be of the same nature in all. Even expert testimony cannot overturn the law of induction. Between this bewildering conflict of evidence, the jury evidently took the only view which comports with common, every-day sense, and that was that a man who showed sufficient sanity to plan and carry out a murder with the intelligence and deliberation shown by Taylor in the killing of Ruth Nollard, was not suffering from a form of insanity which should give him immunity from punishment for his foul crime. The jury evidently thought that Taylor's fits didn't last three days, while he lay at his window with his rifle trained on the street, waiting for his victim, whose offense was that she had refused his unwelcome attentions."—*K. C. Journal.*

The second case was that of a young married woman who shot her husband, and as he fell to the ground mortally wounded, kicked him in the face and spat upon him, all because, as her relatives alleged, he had betrayed her as a lover and refused to support her as a husband, after

a forced marriage. The plea of insanity was used as a defence for the crime. Being called by the defense to examine the woman, and having visited her several times at the jail, it was my opinion that she was not insane, even at the time when she committed the deed, and so testified. The result of the trial ended in her being sentenced to ten years in the penitentiary.

Her lawyers, however, took an appeal, and a new trial was granted by the Supreme Court of Missouri. In the mean time she married again, while her father and brothers were arrested and charged as being accessories to the crime. One of the boys was found guilty and sentenced to serve two years in the penitentiary. In the second trial the woman was acquitted, but not before her brother had served his term of imprisonment. By her acquittal the jury practically said that a crime, taken in its legal acceptance, was never committed; hence her brother had actually served a term in the Missouri penitentiary for a crime that was never legally committed. Is he therefore to be considered a legal convict? And how was it possible for him to assist in the commission of a crime that never, in law, happened? This is a question that, so far, has not been answered.

In 1901 Dr. A. B. Richardson,[4] of the Government Hospital, Washington, delivered an address to this association on the subject of "Graduated Responsibility," in which he maintained that graduated responsibility before the law was not only advisable, but necessary, and that judges and jurors as well as legislators should strive to vary the penalties imposed not only to meet the degree of the criminal act, but also to fit the indidual himself.

That some of the insane are wholly irresponsible for their misdeeds, and justly demand complete immunity from all forms of punishment, all will agree. Moreover, it cannot successfully be denied that a very large number, perhaps the majority of the insane, are, to some extent at least, responsible for much of their misconduct. If, therefore, we can, as a profession, adopt the truth implied in these two propositions originally set forth by Dr. Mercier, viz.: (1) the total immunity of some insane offenders for some acts, and (2) the mitigation of punishment in more or less degree, for all crimes done by insane offenders, we shall not only have taken a great step in advance, but also formulated a more just and equable medicolegal standard for this class of miscreants. The practical importance of securing a consensus of medical opinion regarding these important questions, is therefore obvious, as at present we have no absolute guide or standard of authority to which we can refer.

If, as we are informed, our courts of law desire to know not so much individual as the consensus of medical opinion by those most competent to judge concerning medicolegal questions, who, I ask, has a better right to furnish the solution of these problems than this worthy organization? Unless we are agreed, how can we expect our courts to deal justly with such offenders? In an able article by Dr. C. W. Hitchcock,[5] of Detroit, Mich., on "Mental Responsibility," which he read at the annual meeting of this association in 1900, he states "That he ventures to hope that his desire for the establishment of some sort of standard to which such cases as he reported shall be made to conform, or by which they may be measured, or which at least may serve as a guide as well as for the purpose of comparison, is not entirely utopian or chimerical." Moreover, we should endeavor to set forth what mental conditions should exonerate the insane offender from all form of punishment.

Wherry, in his able article, claims that "the most reliable and efficient test for responsibility when insanity is pleaded as a defense to crime is this: 'Is the crime charged the product and direct result of the insanity alleged?'" "This," he states, "requires that the insanity shall first be proven, but does not indicate that the establishment of insanity necessarily carries with it a condition of irresponsibility." "If the alleged insanity is proven to be associated with a vicious nature, if the crime charged is the product and direct result of hatred or malevolence or evil passions or wicked desires, then the act is vicious in its nature, and vice should never be vindicated simply because disease has given it undue prominence." A man is not responsible for his insanity, but is responsible for his vice. If, on the other hand, conscientious insanity be established, *i.e.*, if the prisoner be the victim of delusions or hallucinations, if his processes of reasoning be imperfect and misleading, though starting from correct premises, or perfect and logical, but based on premises which are untrue, if while drawing conclusions as best he can according to his light, the light becomes a flickering, wavering will-o'-the-wisp that leads him into devious ways where saner men would never go; if he uses the judgment disease has spared in an effort to do what to him seems right, even though it leads to a bottomless pit, then is he not only insane, but honestly and conscientiously so. A man who yields to the dictates of desire is vicious, whether he be insane or not; but a man who acts in response to the dictates of a diseased judgment is conscientious whether he be insane or not. The insane may therefore be divided into two classes—those dominated by desire and those dominated by diseased judgment. The former constitute the vicious insane, the latter conscientious. The one is responsible, the other irresponsible.

According to Dr. F. McDonald,[6] of New York, the real test of responsibility is not a knowledge of right or wrong with reference to the particular act; but, knowing the right and knowing the wrong, has the man the power to choose the right and avoid the wrong? It is therefore not a question of knowledge, but the power to choose between two courses of action.

If he has not such power, then his act is the product of his disease, and he is not responsible. There is, therefore, no legal test of insanity. Every case must be decided on its own merits, but the basic facts are that insanity is a mental disease, and the product of mental disease cannot be a crime.

In conclusion, it would seem highly desirable that this association take some definite action in formulating certain deductions to which we can all agree relative to the mental responsibility of the insane, and thus tend to overcome the prevailing misconception concerning insanity. Such a course would also furnish a reliable guide by which the interests of both law and medicine could justly be subserved, when insanity becomes associated with crime. If these imperfect remarks could serve the means of such a happy consummation, their purpose will have fulfilled their highest mission.

ON THE MECHANISM OF EXOPHTHALMOS.

BY W. G. MacCALLUM,
OF BALTIMORE, MD.,
ASSOCIATE PROFESSOR OF PATHOLOGY, JOHNS HOPKINS UNIVERSITY, BALTIMORE;
AND
W. B. CORNELL, M.D.,
OF TOWSON, MD.;
CLINICAL ASSISTANT, SHEPPARD-PRATT HOSPITAL, TOWSON.

We are still so far from comprehending the nature of exophthalmic goiter that light upon it from any side may be welcome. It has seemed probable that the study of the individual symptoms might be of value in this respect, and we have attempted to determine experimentally the mechanism of the exophthalmos. Since, however, it is after all impossible to be sure that the exophthalmos which one may produce experimentally is the same as that seen in this enigmatical disease, we have contented ourselves, for the time being, with the study of the phenomenon produced in animals by disturbance of the circulation or by the stimulation of the cervical sympathetic, being well aware that although many surgeons hold that exophthalmic goiter is the expression of the continual stimulation of the cervical sympathetic, we are by no means possessed of conclusive proof that this is so.

It is hardly expedient to enter here into a discussion of the nature of all the variety of exophthalmos. Those forms which result from hemorrhage into the orbit, from emphysema of the orbital tissues, from exostoses, tumors or cysts either in the orbit or in adjacent parts of the cranial cavity, from inflammation of the orbital tissues or neighboring tissues, etc., require no special explanation. Nor are we directly concerned with the various forms of pulsating exophthalmos due to arteriovenous communications, aneurisms, etc. In the absence of such definite and obvious causes there still remain to be explained a great many cases among which those associated with exophthalmic goiter are prominent. The greatest variety of explanations, sometimes resting upon experimental work, has been proposed, and these may perhaps be reviewed briefly. These explanations rest either upon vascular alterations or muscular changes.

In especial favor is the idea that if from any cause the venous channels in the retrobulbar spaces become overfilled and dilated an adequate cause of exophthalmos is at hand. This is the basis of the explanation of those cases of pulsating exophthalmos in which arteriovenous communications exists, as may be shown by anatomical investigation (Eales, Schlaefke). Similarly in those cases in which there is thrombosis of the cavernous sinus, there may be an extraordinary protrusion of the eyeball, and this is explained by Eales as due to pressure paralysis of the third, fourth, fifth, and sixth cranial nerves. In those cases, however, as was exemplified recently in the Johns Hopkins Hospital, the protrusion of the eye is associated with the most extreme edema of all the tissues drained by the ophthalmic vein, so that it seems more probable that the exophthalmos is largely due to the edematous swelling of the retrobulbar tissues, although in part directly to the enlargement of the veins.

It has been held by some authors that the widening of the retrobulbar veins, and hence the exophthalmos, is due to vasomotor paralysis (Sattler, Buschan, Matthiesen, Ferri), by others that it is due to active vasodilatation (Schmidt, Rimpler, Ehrich, Rieger and von Forster). Still others ascribe it to the chronic passive congestion resulting from any compression of the veins or obstruction to the return of the blood to the heart. Diseases of the lungs, cervical tumors, bronchocele and the like (Nunneley, Taylor), intrabulbar hyperemia (Eulenberg and Guttmann) and even edema of the membrane of Descemet (Pauli) have been adduced as causes of the protrusion.

Most of these opinions are merely *opinions* and not based on any definite anatomical or physiological observations, but there has also been some experimental work along the same line.

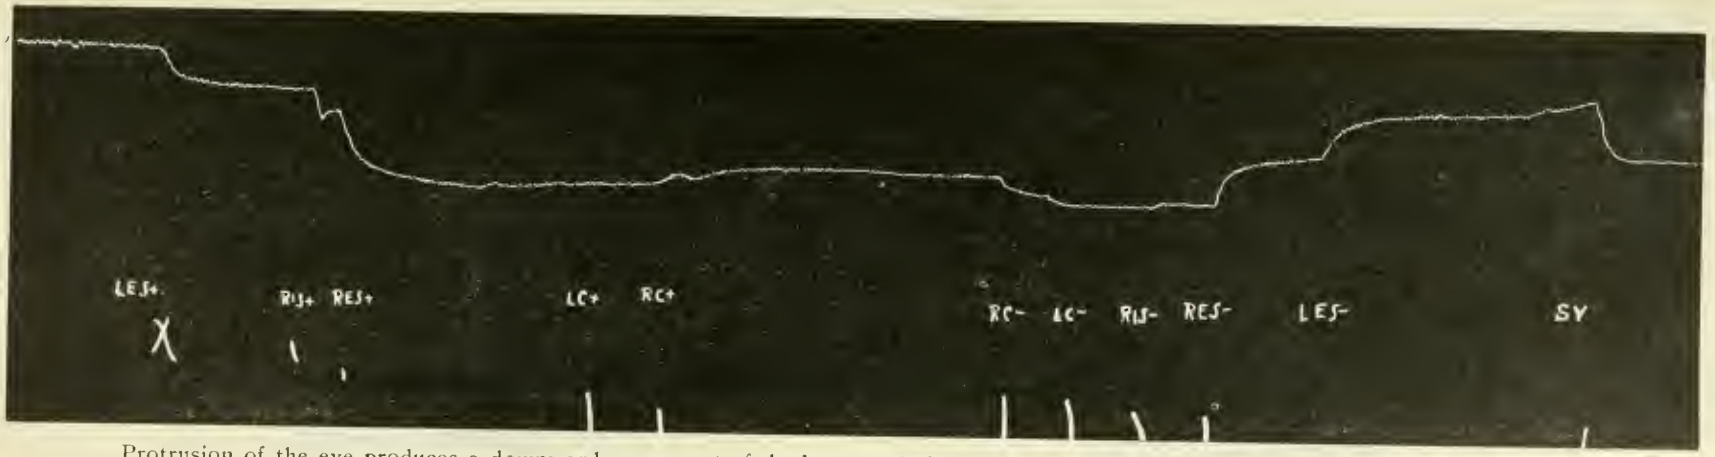
Boddaert, for example, experimented with rabbits with the following results:

1. Section of the cervical sympathetic with ligature of the external jugular on the same side gave exophthalmos on that side lasting a few days.

2. Simple ligation of the external jugular gave only transitory results.

3. The first procedure plus section of the cer-

Chart 1.



Protrusion of the eye produces a downward movement of the lever, and vice versa. + indicates ligation or clamping of the vessel. — indicates the release of the clamp or ligature. R I J, R E J, L E J. Right internal, right external and left external jugular. L C and R C. Left and right carotid. S V. Stimulation of cervical sympathetic, which in the dog is united with the vagus. The sympathetic stimulation was carried out after the eye had returned nearly to its normal position.

Chart 2.

Same lettering as in Curve 1. Sympathetic or vagus stimulation first produced. To the exophthalmos resulting from this there are later added the effects of ligation of the veins.

vical sympathetic on the other side gave double exophthalmos, but more marked on the side on which the vein was ligated, lasting three to four days.

4. Tying both external jugulars gave exophthalmos lasting a few days.

5. In such animal compression of the common carotids caused a recession of the eye, but when the cervical sympathetics were cut this was very slight.

6. Double ligation of the jugulars with double sympathetic section gave exophthalmos lasting ten to fifteeen days and even in traces for two months.

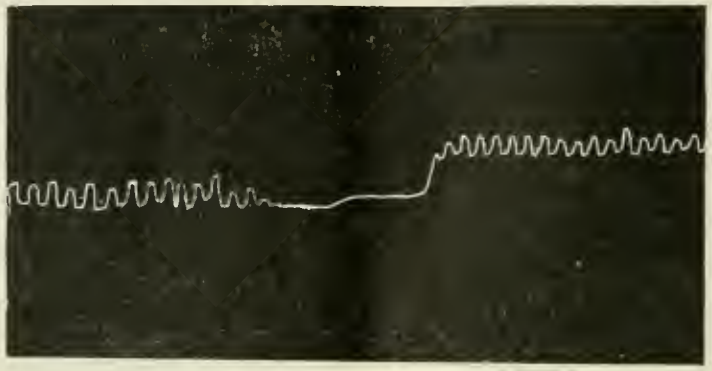
He thought that the orbital muscle is paralyzed by section of the sympathetic, and a retraction of the bulb follows. Probably edema of the retrobulbar tissue causes protrusion secondary to the hypervascularization.

Stilling and Vulpian were able to produce the same changes, but thought that such an experiment could throw but little light upon the exophthalmos of Basedow's disease.

We have repeated some of these experiments with certain variations, and have endeavored to control the results accurately by the use of an apparatus consisting of a lever working about a pivot and recording the movements of the eye on a revolving drum. Such an apparatus was easily constructed of two straws attached at right angles by means of a metal part about which the whole swung on a pivot, the head of the animal being fixed in such a position that the axis of the orbit was vertical. One end of this lever rested vertically upon the cornea, being held in place by a hollow foot of wax, while the end of the other branch, armed with a paper point, traced the curve upon a vertical revolving drum.

Curves drawn with this instrument show respiratory waves, as well as waves which correspond with the pulsation of the heart. It is therefore seen that the position of the eye is slightly modified by both these factors. If now the jugular veins and carotid arteries be separately clamped, very definite changes in the position of the eye occur as are well shown in the curve. Briefly the results may be stated as follows: Ligation or closure of the internal jugular vein on either or both sides produces little or no effect. Closure of the external jugular on the side upon which the eye is being observed produces a marked exophthalmos, which is greatly increased

Chart 3.



Shows marked respiratory and pulse waves. During the application of the stimulus to the sympathetic, which produces the protrusion here marked by a rise in the curve, the respiration is suspended.

Chart 4.

All cervical arteries and veins ligated. Simulation of the sympathetic still produces exophthalmos.

by the subsequent clamping of the external jugular on the opposite side. Closure of the carotid arteries now produces a diminution of the protrusion, which returns, however, to its maximum when they are again released. Finally the release of the external jugular veins allows the eye to sink back to its normal position. All of these phenomena occur, as may be seen in the curve, practically instantaneously. The absolute protrusion in one dog from which we obtained the curves which we reproduce here, when calculated in millimeters, was 3.2 mm. (Charts I and II.)

From this experiment it will be seen that the degree of protrusion produced thus by suddenly clamping the jugular veins is considerable, but would doubtlessly yield after a time to the establishment of a collateral channel of outflow for the blood. If the jugular be left ligated, however, a great edema of the face and eyelids associates itself with the distention of the veins and only gradually disappears. This edema, which apparently involves also the retrobulbar tissue, seems to aid greatly in the protrusion of the eye, and we have thought it an important factor in those cases in which the cavernous sinuses are thrombosed. (Chart III.)

Now it is well known that without any mechanical interference with the circulation of the neck and head one may, by stimulating the cervical sympathetic nerves by means of a current from an induction coil, produce a great exophthalmos (Chart III). Associated with this protrusion there is a retraction of the eyelids and a maximal dilatation of the pupils. Whether there is any alteration in the size of the vessels about the eye and in the retrobulbar space, we could not determine by inspection, but our impression was that there was no definite change. Dr. Randolph was kind enough to observe the retinæ of these dogs with the ophthalmoscope while the sympathetic trunk was being stimulated, but could not make out any alteration in the size of the retinal vessels.

Neverthless the idea that this exophthalmos is due to the distention of the retrobulbar vessels is so deeply rooted that other experiments were made to control these results. (Chart IV.)

In one dog both carotids were tied and the cervical sympathetic stimulated. Quite the same curve was produced as in the dog with the intact vessels. In another dog both common carotids, both vertebral arteries, and the jugular veins were tied (Chart IV). A slight protrusion resulted from the ligation of the veins, which was first performed, but after that the stimulation of the cervical sympathetic trunk produced such a great additional protrusion that there seemed no doubt that its action was independent of the circulation. Finally a dog's head was completely severed from the body and allowed to drain of its blood. Stimulation of the sympathetic now produced exophthalmos quite as marked as in any of the other dogs.

We conclude, therefore, that that form of protrusion of the eyeball which results from stimulation of the cervical sympathetic is entirely independent of the changes in the blood supply. What, then, we may ask, is the mechanism of the process?

Numerous theories as to the action of the muscles have been put forward to explain the protrusion. On the one hand relaxation of the eye muscles and other supports of the eye (Cooper), fatty degeneration and atony of the eye muscles (Traube, Recklinghausen, Bristowe), toxic atony of eye muscles (Lemke), have been held accountable. Fürst, however, quotes a case of ophthalmoplegia to prove that, contrary to Lemke's statement, weakening of the eye muscles produces, if anything, enophthalmos. On the other hand, spastic conditions of the eye muscles (Brüke), overaction of the oblique muscles where the recti are paralyzed (Salomonsohn), have been thought to produce the same effect.

Finally, Sappey, Wagner, and others have thought the protrusion due to the contraction of the so-called musculus orbitalis of Müller. Müller in 1859 described the smooth muscle of the eyelids and also this cone of smooth muscle and elastic fibrous tissue which surounds the eye and by its contraction keeps it forward. Wagner, who attempted in vain to produce exophthalmos in the head of a decapitated woman by stimulating the sympathetic, does not think that the muscle is sufficiently developed in man to have such an action. Th. Harling described in detail the antagonistic action of the muscle to that of the voluntary muscle of the eye; from its funnel shape and its anterior attachments it keeps the eyeball pressed forward. Since, as Müller stated, it is innervated by the cervical sympathetic, the explanation of the exophthalmos may be reached in a simple way. In man, however, he thinks its function chiefly protective. Sappey in 1868 reported a dissection showing that in man the protrusion of the eyeball after stimulation of the cervical sympathetic is due to the existence of smooth muscle fibers which form part of the orbital aponeurosis which constitutes a true fibromuscular sheath. The muscle forms a contractile cuff of conical form, the apex being posterior, so that by its contraction the eye is pressed forward.

We have studied this structure in man and in the dog, and find that, as these authors state, it is far better developed in the dog, where it forms a smooth conical mantle about the eye, continuous anteriorly with the musculature of the lids and forming abundant attachments about the margin of the orbit, passing backward thence, to end about the foramen through which the optic nerve enters the orbit. Nevertheless, this muscular tissue is by no means wanting in man. Here, too, it is continuous with the smooth muscle of the eyelids, and is continued backward in the membrane which lies immediately outside of the bulb (capsule of Tenon).

Anatomically everything seems, therefore, to

point to the possibility that protrusion of the eye might be produced by the contraction of such a muscle.

We have also endeavored to ascertain the extent of the participation of this smooth muscle cone in the production of exophthalmos by direct observation. The top and side of the orbit were removed in a dog and the bulb thus laid bare and freed from surrounding fat. The cervical sympathetic was then stimulated, and we could see a distinct peristaltic wave pass backward throughout the length of this cone, pressing the eyeball forward into the position seen in exophthalmos. Allowing the muscle a few miutes for rest, this could be repeated several times. We then cut with scissors around the middle of this membrane-like cone so as to completely sever the anterior from the posterior half. Stimulation now produced a contraction of the posterior or small end of the cone, which retracted out of sight into the optic foramen, while the eyeball remained stationary.

The simple conclusion for these experiments seems to be that on stimulating the cervical sympathetic nerve the ocular protrusion which results is not due to vascular changes, but to the peristaltic contraction of the cone of the musculus orbitalis which presses the eye forward.

We have, through the courtesy of the surgical staff of the Johns Hopkins Hospital, been able to observe two cases in which, in human beings, stimulation of the cervical sympathetic trunk just below the superior cervical ganglion was carried out. In neither was there any visible exophthalmos, although in both the pupils became greatly dilated on that side. Jonnesco reports, however, the production of exophthalmos in human beings by the use of a strong current in stimulating the sympathetic. (XIII. Cong. Internat. de Méd., Paris, 1900.)

We were further interested to determine whether or not we might produce exophthalmos without pupillary dilatation by stimulating some other part of the sympathtic system. In other words, whether we might find some point at which stimulation would not produce both these phenomena. We therefore traced the sympathetic cord back into the thorax in a cat under artificial respiration, and found that the requisite impulses were produced along a path which could be traced into the second ramus communicans, *i.e.*, into the second ventral root in the dorsal region, but here stimulation produced both exophthalmos and pupillary dilatation, and in spite of the most painstaking exploration of the dorsal and cervical cord, the floor of the fourth ventricle, and the aqueduct, we were unable to find the point we searched for, nor even to produce either of these phenomena from these higher centers. Further search, however, may reveal such a point. Similarly our efforts to produce exophthalmos by stimulating nerves going to or from the thyroid were futile.

In view of the objection which has been raised to the idea that continual stimulation of the sympathetic might form the basis of the exophthalmos in Basedow's disease, we kept up a mild stimulation of the sympathetic in dogs for periods of eight and ten hours, and found that the exophthalmos persisted fairly well all day. A gradually if slightly increasing stimulus seemed, however, to be necessary to maintain the degree of protrusion obtained at first.

We may conclude then that

1. Obstruction to the outflow of blood from the veins of the orbit produces at once exophthalmos, which is relieved by the establishment of a collateral circulation. This process, however, is completed so slowly that in the meantime the orbital tissues as well as the tisue of the face become very edematous, thus adding to the exophthalmos.

2. Entirely independent of any circulatory changes is the exophthalmos produced directly by the stimulation of the cervical sympathetic nerve. This protrusion is due to the peristaltic contraction of the orbital muscle.

From these experiments we can draw no certain conclusions as to the mechanism of the exophthalmos in Graves' disease, but the possibilities are perhaps more closely defined.

Hartford Hospital Gets $500,000.—It was learned on October 3, that by the will of Miss Maria Terry, who died at Venice a month ago, the Hartford Hospital will receive approximately $500,000. A director of the hospital, when asked to confirm the report, said that the institution had been remembered by Miss Terry, and he thought the bequest would amount to about half a million dollars.

SOME NOTES ON A CASE OF ERYTHROMELALGIA; WITH TREATMENT.

BY I. W. VOORHEES, B. S.,
OF NEW YORK;
COLLEGE OF PHYSICIANS AND SURGEONS.

The points in the case about to be described, while not in themselves especially remarkable, may nevertheless prove of some interest as illustrating the peculiar conditions met with in this distressing disease.

At the time of onset the patient was a woman of fifty-seven years, and the mother of three children who are still alive and well. She came of a family in which alcoholic or other indulgence was practically unknown. Her father died of apoplexy, and for many years her mother suffered with nephritis, which terminated fatally when she was in her fiftieth year. A brother died of carcinoma of the inferior maxillary, and a sister of a complication of diseases. It is interesting to note that no history of mental or nervous trouble was obtainable on the side of either father or mother. The patient had the common diseases of childhood, save diphtheria and scarlet fever. At twelve years she had a severe attack of acute articular rheumatism, with an associated pericarditis, but recovered completely and never had a recurrence.

Her first child was born when she was twenty-three years old; it was a forceps delivery and she is said to have had a very "hard time." Then neuralgia of the trigeminus set in and continued for twelve years, being of so severe a type that she was confined to bed for three days in every week. The second child was born four years after the first; the labor was fairly easy and recovery uneventful. The third child was born ten years after the second, when the patient was thirty-seven years old, previous to which all neuralgia had ceased spontaneously. There was never any further pain in the head. Menstruation began at fourteen; it was difficult at first and compelled the patient to leave boarding school; after it became established it was always regular in appearance, duration and quality until her forty-seventh year, when the menopause took place.

The onset of the disease in question took place in 1899. At that time the patient experienced sharp and severe pain in the great digit of the right foot, which, in her own language, resembled very closely the sting of a bee. There was, from the first, extreme sensitiveness to touch, and it was at times impossible to keep a stocking on the foot. The pain was worse at midday, and usually reached its height when the patient came to the dinner table, gradually lessening during the afternoon, and allowing her to sleep fairly well at night. Inspection showed some swelling of the entire toe; the skin on the dorsum was pale and had a varnished look, while on the plantar aspect there was a mottled appearance not unlike that of frost bite. The toe was exquisitely sensitive, and so hot that an ice-cloth, when it was possible to apply it, would dry so perfectly within ten minutes that it gave the appearance of being starched. The patient was obliged to walk on the heel. These observations were made during the first month.

It should be emphasized at this point that throughout the most distressing and uncontrollable condition was the pain. By September, 1899, this symptom had greatly increased, both in frequency and severity, but was not worse at any particular part of the day. It began to interfere with sleep, and was less easily governed by cold; occasionally, hot cloths seemed to give greater relief. The symptoms from this time on were somewhat masked by the use of morphine, which had to be resorted to in the absence of relief from any other drug.

On November 1 the patient went to the Presbyterian Hospital in New York, where she was seen by Dr. M. Allen Starr, who made the diagnosis. She was put on potassium iodide, 20 grains, three times a day; the leg was slightly elevated in a comfortable position, and a bed-rest made to keep the covering free from contact with the feet. In two weeks she became dissatisfied and went to her home in the country, where the same treatment was continued.

Local examination revealed the same condition as was described above, with extension to the ball of the foot. Upon being questioned she admitted the presence of some slight pain in the great toe of the left foot, but regarded it as unimportant. Electricity proved that degeneration was rather advanced in both feet, but in the right more than in the left. At this time the patient walked about the room on her right heel, or traveled about with the right knee on a small chair which she pushed along. She soon took to bed, however, and remained there several months.

The heart was moderately hypertrophied, but about in its normal position; occasionally it skipped a beat, or perhaps two or three beats, and then would become irregular, beating faster and faster till it finally slowed down to normal. No organic murmurs were discoverable. The pulse was strong, fairly regular, slow, full and of increased tension. The radial artery was thickened, but compressible; lungs, normal. Loss of memory was becoming noticeable to the patient, and was marked even to the casual observer. She had always possessed a very good memory. Sight and hearing were good. Reflexes were slightly diminished. There were no twitchings, and no peripheral disturbances, save in the diseased region. Symptoms in the alimentary tract were probably due to morphinism; the mouth was dry; tongue, furred; appetite, lost; digestion, imperfect, with formation of a great deal of gas which was pased *per orem*.

The desire for morphine now became irresistible at exactly the same hour each day, and was evidenced by a very abundant watery secretion from the nose, by the belchings of large quanti-

ties of gas, a "gone" feeling in the stomach, and heart weakness. If unrelieved, collapse symptoms became imminent; but an eighth of morphine caused immediate disappearance of all these effects in from twenty to thirty minutes. It is necessary to state, however, that at no time did the amount of morphine administered exceed five-eighths of a grain in twenty-four hours, and the average was about three-eighths. The bowels moved daily, resort to cathartics or enemata being necessary only a half dozen times during the entire illness of four years and nine months.

In the winter of 1900 the symptoms were most marked, and the severity of the disease process may be said to have reached the high-water mark. Examination showed that all the toes of the right foot were involved, and had a peculiar purplish tinge on the plantar aspect, while the dorsal aspect looked pale and shiny. The nails also had a purplish appearance with a dull waxy luster. The ball of the foot had a mottled purplish color, which was most prominent over the first metatarsophalangeal articulation. In the hollow of the foot there were several reddish patches, irregular in shape, reminding one of a spatter of red ink, and varying in size from a ten-cent piece to a quarter. The sides of the dorsum of the foot also had three or four patches, but as remarked before, they were not present on the dorsa of the toes. There were four or five spots on the posterior aspect of the leg, and one or two on the thigh, but none were situated on the anterior aspect. These spots were darker in color than those on the foot, and had the appearance of an old contusion of the skin, being partly yellowish or bluish.

Very soon the pain left the right foot, and the symptoms it had presented began to disappear. The swelling of the toes subsided, the spots disappeared, desquamation took place, and there was the look of new nails growing out from the old matrices. The same improvement took place in the left; all acute symptoms subsided, and the patient passed into a condition of comparative comfort. Numbness and "queer" feelings continued for about a year, during which the patient enjoyed good health and regained complete use of her limbs which had atrophied from disuse. There was never the slightest evidence of bony deformity.

In February, 1903, she experienced unpleasant sensations in her back and legs. There were chilly feelings which soon developed into actual chills, coming on every morning on getting out of bed, and lasting for an hour or more. Stiffness and soreness in the joints soon followed, and one month later severe pain began in the hallux of the left foot. The left knee became stiff and sore, but there was no limitation of either active or passive motion, save the discomfort of the operation. There was also considerable pain in the left hip which lasted for one month and then subsided. The fear of gangrene, which was at one time entertained proved to be a groundless one, for this condition never developed. In June the patient began to be confined to bed, and suffered for four months all the tortures that accompanied the progress of the disease through her right side; the sequence of involvement, appearance on examination, and subsidence, being precisely the same.

The symptomatic treatment of this condition may be said to have been a total failure, since nothing stopped the progress of the disease, and even morphine finally failed to control the pain. Such local applications as the much-vaunted antiphlogistine were intolerable, and had to be washed off immediately after application, giving the patient much additional pain in the process. The iodide of potassium alleviated the condition for a time, but had to be stopped because of its severe action on the stomach. Nitro-glycerin was tried, but was soon abandoned. In securing relief, two conditions were to be met: First, to control the pain; second, to control the craving for morphine. The patient was really starving because she could neither take nor digest food suitable for the maintenance of life, even broths, peptonized milk, and light custard being rejected. As an experiment we began to use fluid extract of ergot in 30 minim doses, three times a day, gradually increasing to a dram dose. Within ten days the pain began to lessen, and the dosage was reduced until the drug was no longer necessary.

At the same time it was deemed advisable to give some preparation of strychnine, since this drug is a synergist of ergot, tones up the nervous system, acts directly on the digestive apparatus, and is somewhat antagonistic to morphine. Accordingly, one-thirtieth grain of the sulphate of strychnine was given three times a day, as this seemed the most convenient form of administration. The morphinism was treated by gradually cutting down the dosage and administering an equivalent amount of dionin and peronin, using each a week at a time, entirely without the patient's knowledge, of course. At the end of three weeks the appetite had returned completely, the morphine habit was broken, and the drug discontinued. No other treatment was henceforth employed, save good substantial food and the continuation of the strychnine for two weeks longer.

For three months the patient gained in strength. She got out of bed, and recovered complete use of her limbs without the interposition of any symptom previously manifest. During this time there was thickness and indistinctness of speech, with amnesic aphasia and agraphia. At times the patient seemed dazed and unable to answer simple questions directly; she was perfectly conscious of her surroundings, however, and called each member of the family by name. There was apparently complete loss of memory for persons and objects which she had not seen for an interval of ten years. Within this limit the memory was fairly good. The

mouth was somewhat drawn down toward the right side, but there was no motor paralysis elsewhere; she had perfect control of the arms and hands. Occasionally, the fingers felt numb, and the nose would itch and become quite red, but no pain could be elicited. The patient's disposition became entirely changed, she was mild, gentle, never lost her temper, and was inclined to be optimistic. These points were especially noticeable to members of her family. On December 27 she was seized with violent coughing and choking at the dinner table, and upon examination was found to have had a typical apoplectic seizure, from which she died within twenty-two hours. It is greatly to be regretted that no autopsy was obtainable.

The points to be emphasized in this case are: (1) The acute onset; (2) the severe pain; (3) the gradual progress; (4) the long periods of intermission. Looked at in perspective it is doubtful if the treatment finally employed had as much influence on the disease as was at first thought from the rapid subsidence of the symptoms, as she had had two previous intervals of freedom from pain. Since other cases reported in the literature differ in so many respects from this, there is certainly no specific remedy available.

355 West Fifty-sixth Street.

A FACTOR IN THE CAUSATION OF EMACIATION IN TUBERCULOSIS OF THE LUNGS.[1]

BY HAROLD M. HAYS, A. B.,

OF NEW YORK;

FROM THE DEPARTMENT OF PHYSIOLOGICAL CHEMISTRY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

It is a well known truth that emaciation is more characteristic of tuberculosis than of any other disease. In fact the words phthisis and consumption derive their origin from this one symptom.

But very little investigation has been undertaken to explain this emaciation. Some authors ascribe it to an increased metabolism "inseparable from the febrile process." Others claim that it is due to a specific toxin which increases the catabolic activities of the cells.

To investigate the relation of digestive activity to emaciation in tuberculosis, the experiments about to be enumerated were made.

An attempt was made to ascertain the activities of the digestive glands of patients suffering from tuberculosis of the lungs by comparing them with the activity of the digestive glands of normal persons and the glands of patients suffering with malignant disease.

As it was almost impossible to obtain the gastric juice from a sufficient number of patients, it was necessary to take a secretion which could easily be obtained. So the saliva was determined upon as the medium for investigation.

1 The writer is indebted to a number of gentlemen for their encouragement and assistance. He is under especial obligations to Dr. Wm. J. Gies, Dr. Ira S. Wile, the Resident Physician at Seton Hospital, and Dr. G. Alfred Lawrence, of the Skin and Cancer Hospital.

The saliva is an excellent secretion for experiments of this kind. In impaired digestion, it shows less change than the gastric or pancreatic secretions. Therefore, there is all the more reason for believing that a pathological state of this fluid is of the utmost importance as an indication of a change in the system. Those pathological changes which have been found to exist in the saliva have usually been specific changes due to some extraneous substance and not to an altered state of the secretion, *per se*. Among the extraneous substances might be mentioned potassium iodide, urea, bile salts, etc. On the other hand Fenwick claims "that the sulphocyanide of the saliva is a measure of the functional activity of the nutritive organs, and that it is increased in general whenever an unusual demand is made on them by the necessities of the system, provided these organs are capable of responding to the call, as in the early stages of acute inflammation, of cancer, phthisis, etc. The quantity is diminished in all conditions where the nutritive organs are unable to supply the requirements of the system, as in the later stages of phthisis and malignant disease."—(Von Jaksch, Clinical Diagnosis).

One may ask what defense may be sought in using the saliva as an indication of the activity of the other secretions of the alimentary canal. In the first place, the general tendency is for the whole gastro-intestinal canal to be more or less affected when one individual portion suffers. For example, there is an excessive secretion of saliva in pyrosis and a diminution in the amount of secretion in fevers. The fact is well established that in any pathological condition of the stomach or intestines, the rest of the alimentary canal is likewise in an altered condition, either organically or functionally. This may be explained in one or two ways. Either the specific function of the *whole* canal is for digestion and assimilation of food or else the various nervous centers of digestion in the central nervous system and in the sympathetic ganglia are so associated and correlated, that one centre exercises an influence over the others.

The saliva may be taken as an indication of the secretory activity of the whole gastro-intestinal canal for the following reasons:

1. The saliva shows less change in impaired digestion than the other secretory fluids of the gastro-intestinal canal.

2. In some diseases of the gastro-intestinal canal, the saliva undergoes a pathological change.

3. The centers for the secretory apparatus are so intimately connected in the nervous system, that one set of organs is governed reflexively by the condition of the others.

Accepting the saliva as an indicator of the glandular activity of the gastro-intestinal canal, the following experiments can then bear considerable weight on partially determining the cause of emaciation in tuberculosis of the lungs.

One objection may be raised. In the experi-

ments, the tubercle bacillus would invariably be found in the saliva. Now is it not possible that the presence of the bacillus in the secretion may be of some import? This point may be dealt with summarily. The saliva as found in the mouth, is so full of bacteria, yeasts, fungi, etc., often the tubercle bacillus itself being present, that it can hardly be asserted that this one species of bacteria can have any influence on the starch digesting power of the saliva.

The writer's technic carried out in the experiments was as follows:

Method of Collecting the Saliva.—The saliva from the tuberculous patients and the healthy individuals was collected in the forenoon; the saliva from patients with malignant disease was obtained in the afternoon. Each patient was supplied with an ordinary elastic band which was sterilized by boiling. This was chewed upon for ten minutes or until 10 c.c. of saliva was secured. The saliva was expectorated into a clean cup and from this was poured into a two ounce bottle containing a little thymol. The specimen thus collected could be kept indefinitely. The bottle was tightly corked and stowed away for a few days for subsequent examination.

At the time of the experiment, the saliva was filtered. Six c.c. of the filtrate was poured into a two ounce bottle. This was diluted up to 60 c.c. with distilled water, thus making a 10 per cent. salivary solution. The specimen was then ready for use.

Method of Procedure for Determination of Amylolytic Power.—It was found that the best method was that of titrating the digested fluid into a known strength of Fehling solution, used according to the method of Pavy.

Solution 1. 79.28 grams of crystals of copper sulphate are thoroughly triturated and added to 800 c.c. of distilled water. After the salt is dissolved, the solution is brought up to 1,000 c.c. with distilled water.

Solution 2. 346 grams of sodium potassium tartrate are dissolved in 400 c.c. of distilled water and 250 grams of potassium hydroxide in 400 c.c. of distilled water. The two are combined and distilled water is added up to one liter. In the experiments equal parts of 1 and 2 were used.

Test of the Reducible Power of the Fehling Solution.—Ten cubic centimeters of the mixed solution here used was titrated against 2.5622 grams of thoroughly dried glucose, dissolved in 100 c.c. of distilled water. It was found that .0538062 grams of sugar reduced 10 c.c. of the solution.

Pavy Modification of Fehling's Test.—Pavy's modification throughout the experiments, consisted in making an ammoniacal copper sulphate solution as follows:

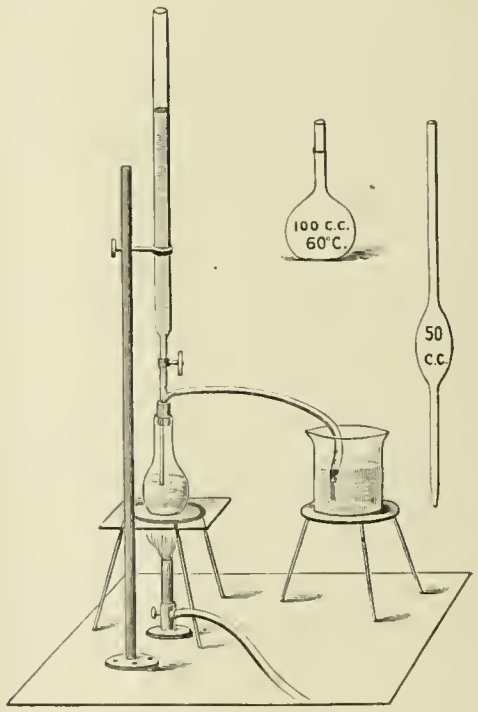
30 c.c. of Fehling No. 1.
30 c.c. of Fehling No. 2.
150 c.c. of 10 per cent. ammonium hydroxide.
290 c.c. of distilled water.
500 c.c. of the Pavy solution.

The solution was made up fresh every day, 50 c.c. of Pavy solution being used for each titration. It will thus be seen that 6 c.c. of Fehling solution was used each time.

The Pavy modification has many advantages in accuracy over the ordinary Fehling test. In the first place, the copper sulphate is in a more dilute solution. Secondly, the color change is in the solution and no precipitate is formed. Thirdly, the blue changes to a colorless solution. And fourthly, no oxidation from the air can possibly take place as the ammonia vapor occupies the space above the fluid when used in the apparatus about to be described.

Description of Apparatus.—A flask of 300 c.c. capacity is placed upon a tripod over a Bunsen burner, wire gauze serving as a protection from the flame. A 50 c.c. burette, graduated in tenths,

Fig. 1.



Apparatus used for titrating according to the Pavy method.

is connected with this flask by means of rubber and glass tubing, passing through a closely fitting two-holed stopper. Upon another tripod is a beaker containing distilled water. A short piece of glass tubing passes through the second hole of the stopper and is connected with a piece of rubber tubing whose free end is closed by a short glass rod and which is put into the beaker. Just above the closed portion of the tube, a small linear opening is made to allow the ammonia to run through the water. Fig. 1 represents in a crude way the apparatus used.

Preparation of the Digested Fluid.—Powdered arrowroot starch was taken as the material for digestion. This was finely powdered and exactly

one gram was weighed out and then poured into a graduate 100 c.c. flask in which 90 c.c. of distilled water had been measured as follows: 100 c.c. of distilled water was poured in up to the mark on the neck of the flask and then 10 c.c. withdrawn by means of a pipette. When the starch had been added, the solution was thoroughly shaken and heated to boiling, being constantly stirred so as to make a starch paste. The paste was then poured back into the flask and allowed to cool at room temperature.

As was noted before, the saliva had been made up in a 10 per cent. solution. To the starch paste was now added enough saliva solution to fill the graduated flask, thus one per cent. of saliva being used. This new solution was then thoroughly shaken and immediately transferred to an incubator at 100.4 to 104° F. and allowed to digest for exactly one-half hour. At the expiration of this period, the solution was quickly transferred to a beaker and boiled thoroughly so as to inhibit the action of the enzyme. One can now wait a few days before titrating for the amount of sugar.

Estimation of the Amylolytic Power of the Saliva.—The burette is thoroughly rinsed with a little of the digested solution. 50 c.c. of the Pavy solution is placed in the flask. The burette is filled with the digested mixture, which must not be used in a warm condition. The rubber and glass tubings, having been connected to the burette, the digested fluid is permitted to flow from the burette until a few drops escape from the lower end of the glass tubing. The stopper with its two glass tubes is now firmly inserted into the flask. The fluid in the flask is heated to boiling and the digested mixture is allowed to flow in to the Pavy solution, drop by drop until the blue color has entirely disappeared. The reading from the bottom of the meniscus having been previously ascertained, a second reading is taken in the same way and the result calculated by finding the difference between the two.

Five titrations of the same solution were made in each case and an average of the closely agreeing readings taken as approximately accurate.

Calculation of the Amount of Sugar.—The calculation of the amount of sugar was reckoned by the number of cubic centimeters of the digested fluid used. For example, 21.3 c.c. of solution being used, the amount of glucose equals 152 mmg. reckoned as follows:

10 c.c. Fehling reduces .0538062 grams of sugar.
6 c.c. Fehling (the amount used) reduces .0323 grams of sugar.
21.3 c.c. equals .0323 grams sugar.
1 c.c. equals .0015217 grams sugar.
100 c.c. of solution (1 gram starch) equals 152 mmg. glucose.

The amount of maltose is easily reckoned from this. Ordinarily 10 c.c. of Fehling reduces .0778 grams of maltose when 10 c.c. of the same Fehling will reduce .05 c.c. of glucose. So .0778:.05::x:.0538062 or 10 c.c. of the Fehling used reduces .083722447 grams of maltose.

Then glucose:maltose::1:1.556. Therefore, multiplying the milligrams of glucose by the factor 1.556 will give the milligrams of maltose.

Method of Testing the Alkalinity.—Ten c.c. of the 10 per cent. filtered saliva was used. Congo red and lachmoid were the indicators. There was practically no difference in results when an average of five titrations was made. The ordinary titration apparatus (burette, etc.), was used, the titration being made with hydrochloric acid of a known strength. The results were read in tenths of a gram and then transposed into milligrams. Each cubic centimeter of acid neutralized .0025 grams of NH_3, whence each c.c. of hydrochloric acid equalled .00502 grams of sodium carbonate, which was taken as the constant alkaline medium in saliva. The results were ascertained as follows:

1 c.c. HCl = .0028 grams N.
N = 14 H = 3
Therefore .0034 NH_3 = 1 c.c. HCl.
$NH_3 + HCl = NH_4Cl$
17 36.5
Therefore 17:36.5:: .0034:x
X = .0073 grams HCl in 1 c.c.
$Na_2CO_3 + HCl = 2NaCl + H_2O + CO_2$
106 73
Therefore 106:73::x:.0073 grams.
And each cubic centimeter HCl = .00502 grams Na_2CO_3.

For example, 10 c.c. of saliva neutralized .5 c.c. HCl. So 1 c.c. of saliva equaled .05 c.c. of HCl. The number of mmgs. of ammonia would equal

1 Patients in the early stage of the disease.

.00037 grams of HCl which would equal .00251 grams, in terms of sodium carbonate.

The Saliva from Tuberculous Patients.—Table 1 shows in tabular form the results of twenty individual cases examined. The physical characteristics of the saliva showed it to be thicker than normal in consistency and usually darker in color. It often contained shreds of mucus and foreign material. After filtration and dilution, the physical characteristics were practically those of the normal.

It will be noted that the amount of maltose obtained varied between 228.7 mmg. and 449.7 mmg. with 1 gram of starch digested by 1 c.c. of saliva. The average digestive power for the twenty cases was 15 c.c. of digested fluid reducing the 6 c.c. of Fehling solution contained in the 50 c.c. of Pavy solution. Cases A, R and T were patients in the early stage of the disease. Here the digestive power was *less* than in the other case.[1]

The cause of the apparent contradiction to what might be expected, is not easily determined. Yet many suppositions might be brought forth to account for the fact (that the digestion is better in the advanced cases), which appear to lead in the right direction. In the first place, cases A, R and T were patients at the Vanderbilt Clinic and at the Roosevelt Hospital Out-patient Department. The other seventeen were quartered at the Seton Hospital where consumptives find a home. The former were patients who were walking about, receiving little care, other than what the Clinic could give, probably exerting energy at the expense of their tissues. The latter were in bed, under good medical supervision and nursing, and on a well regulated diet.

Another factor may explain this point. The former class of patients were probably suffering from the overwhelming effects of some toxic agent (toxin?). The secretory cells of the digestive system had to suffer with the rest of the body. It is a well known fact that the body may adjust itself to a certain extent to a certain pathological condition. No doubt that was what happened in the latter class of patients. The toxic agent either had become less poisonous in its action or else enough antagonism had been brought to bear by the body to allow the physiological functions of the organism to tend toward the normal. This exactly accords with the expressed opinion that the emaciation is less in the chronic cases than in the acute cases or at the beginning of the disease, when the body finds itself in the position of a gateless barrier into which the antagonistic bacteria are throwing forth their deadliest weapons. But the barrier becomes better fortified by having to withstand repeated onslaughts until the poisonous weapons, in some directions at least, have lost a part of their deadliness.

1 The fact must be borne in mind that the less digestive mixture used, the better is the digestion, as it takes a less amount of the digested solution to equalize the 50 c.c. of the Pavy solution.

The writer has spoken about some toxic agent. What this poison, which seems to permeate the system, is, we are at the present time unable to say. As fever was present in all these twenty cases, it is highly probable that this had something to do with the impaired digestion. (The digestion was impaired as will be shown later on.) This factor of fever may also explain to a great degree the cause of the more greatly impaired digestion in the cases A, R and T; for in any fever, any active bodily exercise, lack of rest, and lack of proper attention to the digestive organs will produce an impairment of the activity of these organs. Whether fever is due to some toxic agent, either in tuberculosis or in any other disease, remains for the future years to discover.

TABLE II.

Chittenden and Richard's Table or Normal Saliva.

	Time.	Mmgs. maltose	ALKALINITY as Na_2CO_3	ALKALINITY as Mmgs. H_2SO_4 to neutralize 1 grm. of saliva
R	Before Breakfast.....	523.4	0.173	0.83
	After Breakfast.....	511.8	0.127	0.61
M	Before Breakfast.....	585.0	0.117	0.56
	After Breakfast.....	468.6	0.102	0.49

Investigating the alkalinity of this saliva, it was ascertained that 20-60 mmgs. of HCl were required to exactly neutralize 1 c.c. of saliva. This alkalinity is rather higher than normal, the average here being 40 mmg. A fact of considerable importance will be noted, that the alkalinity is greatest where the digestion is most impaired, as for example Case A where the milligrams of maltose were 236.51 and the alkalinity 50 mmg. of HCl needed to neutralize the fluid and O where

3 *Cf.* Table I.

the milligrams of maltose were 425.8 and the alkalinity 20 measured in terms of HCl. But there was considerable variation as is shown by Case C where the milligrams of maltose were as high as 449.7 and the alkalinity 37.5 in terms of HCl.

The digestion being better where the solution approaches the normal, entirely accords with the views of Chittenden and Smith (Yale College Studies, Vol. I) and Hammarsten (Physiological Chemistry) as to the action of normal saliva. "From a number of experiments by Chittenden and Richards (*American Journal of Physiology*, Vol. I), it is seen that the variations in amylolytic power are not dependent upon the amount of alkaline salts; but that, more likely, the alkaline salts are increased where there is a greater degree of amylolysis, showing a higher degree of concentration of the enzyme" (Hays, Medical News, Vol. 84).

But there are enormous degrees of varieties both in amylolysis and alkalinity. For example, the amylolytic power is greater before breakfast than after the morning meal. This is confirmed by the observations of Chittenden and Richards and is shown in Table II. "It would appear that saliva secreted after a period of glandular inactivity, as before breakfast, is ordinarily possessed of greater amylolytic power than the secretion obtained after eating. Before and after dinner, however, the difference in amylolytic power is less pronounced, a fact which might be expected of the short period of recuperation between the breakfast and dinner and because of the more or less constant stimulation of the salivary glands during the waking hours."

But even if we take these factors into consideration, it must still be admitted that in the cases referred to, the digestion *was* impaired, as may be noted by reference to Table III of normal saliva; and also that the alkalinity was a great deal higher than normal.

Amylolytic Power and Alkalinity of the Saliva from Ten Healthy Persons.—The amylolysis in this set of experiments, was ascertained with the same precautions. The digestion was between 381.2 and 517 mmgs. of maltose, the average being 10.6 c.c. of digested fluid to react to the 6 c.c. of Fehling contained in the 50 c.c. of Pavy solution. The most impaired digestion was in Case J where 13.2 c.c. of digested fluid were used to react to the Fehling. The writer was not surprised at this as the person from whom the saliva was taken, looked as if he might be in the incipient stage of tuberculosis and was actually used as a test case. The best digestion in this series was in Case B who was a good healthy person. Case D was a child of twelve years who was taken to meet all exceptions and Case F's saliva was taken after smoking for the same reason.

It will be seen that the average amylolysis in the tuberculous cases was 1.4 c.c. of digested fluid above that of the normal set, measured in terms of the amount of digested fluid needed to equalize the 6 c.c. of Fehling solution and that over 100 mmgs. less maltose was thus obtained in the former set of cases, showing a decided diminution in digestion and in the activity of the secretory cells in the tuberculous patients.

The alkalinity in this normal series varied between 15 and 35 mmgs. of HCl, the average being 25 mmgs. Comparing this with the tuberculous

5 Carcinoma of breast, nine months duration.

cases, it is again to be noted that the average alkalinity is only one-half as great. But Case B shows the best digestion and yet the saliva was the most alkaline. It can only be taken as one of those exceptions that proves the rule. No doubt there was a greater concentration of the enzyme ptyalin than in the other healthy persons, which was proportionately equal to the excess of alkaline salts and not in an inverse ratio to it.

Table V.

Comparison of the Averages and Extremes in Digestion in the Three Series of Cases.

Series.	Amylolysis. Extremes. In terms of mmgs. maltose.	Amylolysis. Average. C.c. of digested solution to equalize 6 c.c. Fehling	Alkalinity. Extremes	Alkalinity. Average.
			Alkalinity of saliva in terms of mmgs. HCl. 1 c.c. HCl=.00727 grms. NH_3.	
1. Tuberculous.	228—449	15.	20–60	40
2. Normal	381—517	10.6	15–35	25
3. Tumor cases.	529—564	9.12	15–25	20

The less the amount of digested fluid used in titration, the greater is the percentage of sugar.

Amylolytic Power and Alkalinity of Saliva from Five Patients with Malignant Tumors.—For the matter of comparison, these five cases were taken where there was some cachexia but not as great an emaciation as in the case of tuberculosis. All the patients were the subjects of well-marked malignant disease. This is explained in Table IV. The first three cases were

under X-ray treatment, the fourth had a recurrent carcinoma of the breast which was to be operated upon and the fifth was in the Skin and Cancer Hospital awaiting operation.

The writer was prepared to meet with the same results as in the tuberculous cases, but great was his surprise to find that the digestion was *better* than normal. In this present paper it is not his duty to discuss this fact.

The amylolytic power varied between 529 and 564 mmgs. of maltose, the average being 9.12 c.c. of digested fluid needed to equalize the 6 c.c. of Fehling solution. The best digestion was in B where the saliva contained some admixture of blood which came from inflamed gums. It is seen that the alkalinity in this case was 15 mmgs. in terms of HCl and, considering that the blood contains alkaline salts, it may be assumed that the alkalinity of the saliva itself was even less than this. This again conforms with the statement that salivary digestion is better when the solution is nearly neutral.

The alkalinity of the saliva of these patients suffering from malignant disease varied between 15 and 25 mmgs. of HCl neutralized, the average being 20 mmgs.

Comparison of results in the Three Series of Cases.—Table V shows the extremes and averages both in amylolysis in the tuberculous and normal cases and in the cases of malignant disease. Comparison of the amylolysis in terms of maltose, shows that the degree of digestion in the tuberculous cases is far less than in the other two. In fact we see that there is a difference in the lowest extremes of 153 mmgs. of maltose, comparing the result with the normal; and a difference of 301 mmgs. of maltose, comparing it with the last set of cases. The best digestion in the tuberculous cases was only 68 mmgs. greater than in the lowest of the normal cases; and it must be remembered that this low normal case was already commented upon (Case J, Table III) a few pages before. Taking the next lowest normal, we find it to be 449.7 mmgs. of maltose, *which exactly equals the best digestion* in the first set of cases.

Taking the average digestion in terms of the number of cubic centimeters of digested fluid needed to equalize the 6 c.c. of Fehling in the 50 c.c. of Pavy solution, the result is noted that the digestion in the tuberculous cases is 15 c.c. against 10.6 c.c. in the normal, showing a digestion of one-half again as much in the latter set of cases.

A comparison of Series 1 and 2 with Series 3 shows a still more astonishing result. The variations in amylolysis in the tumor cases was comparatively slight, being between 529 and 564 mmgs. of maltose. Even the lowest set of figures was higher than normal and therefore much higher than in the tuberculous cases. The differences between the lowest figures in Series 1 and 2 is 148 to 47 mmgs. of maltose. And the difference between Series 1 and 3 is 301 to 115 mmgs. of maltose. But even this digestion in the last set of cases is not too high for normal as is shown by comparison with Table II. And considering that the class of persons in Series 2 and 3 were different, but the same in Series 1 and 3, the discrepancy may thus be partially accounted for. Taking note of the average in terms of the amount of digested fluid used to equalize the Fehling solution, we find 9.12 c.c. against 15 c.c., the digestion being over one-half again as good in the tumor cases as in the tuberculous cases and almost one-tenth better than in the normal cases.

A comparison of the relative alkalinity is now in order. In Series 1, the extremes were 20-60 mmgs. in terms of HCl neutralized, the highest being 25 mmgs. above the highest in Series 2 and 35 mmgs. above the highest in Series 3. The least alkalinity did not approach the neutral point by 5 mmgs. to what it did in Series 2 and 3, showing that even taking the extremes, the tuberculous saliva was more alkaline than the saliva in the other two sets of cases. Taking the average, we find the alkalinity one and one-third times as great in the first as in the second series and twice as great as in the third series. This again agrees with the assertion that the salivary digestion is better where the saliva tends toward the neutral.

Conclusion.—We have definitely proved that the saliva of patients suffering from tuberculosis of the lungs is greatly impaired in digestive power. The salivary digestion being impaired, the question now arises as to the condition of the secretions of the rest of the gastro-intestinal canal. It seems to the writer perfectly feasible to take the salivary digestion as an index of the activity of the other glands of the gastro-intestinal canal (as stated before), first because the secretory centers of the whole digestive system are so closely associated, and secondly because a pathological state of the saliva means a profound alteration of the digestive system.

In accounting for the cause of this impairment in digestion we can but theorize. The presence of a specific toxin in tuberculosis has not yet been proved to exist. And yet the alteration in metabolism in this disease appears to be due to the effects of some toxic agent which is either the specific toxin of tuberculosis or else is the result of the febrile process. As was noted before, all the tuberculous cases examined had some fever. There was no fever present in the individuals in the last two series. Is it not possible then, for the diminution in digestive power to be due to the presence of this febrile process since we know that in fevers in general there is an alteration in the digestive mechanism?

The statement has been made to the writer that patients suffering from tuberculosis are fed frequently and in great quantities and that these same patients appear to be able to absorb and

assimilate all the food given them. Can this be possible if the digestive juices are impaired? It certainly is possible if we assume that it is the quality and not the quantity of digestive secretion which has suffered in tuberculosis. If the glands, by constant stimulation from an increased diet are capable of secreting an extra amount of fluid, digestion can then be accomplished to meet the varying needs of an increased metabolism. But one of two things must happen under these circumstances. Either the digestive system must wear out under the increased toil or the body must accustom itself to the increased labor. If absorption and assimilation of food does take place under the increased feeding in tuberculosis, it is probable that the digestive system of the patient accustoms itself to the increased toil and secretes more fluid but fluid of a poorer quality.

The question has been asked "If the variations in normal saliva are so great and the excursions so extreme, how is it possible to make a just comparison?" The experiments enumerated invalidate this point, for it is shown, even taking the extremes into due consideration, that the salivary digestion in tuberculous cases is diminished.

Noting the alkalinity, we find it greater than in the normal cases, but still the same rule holding true that the digestion is better when the saliva approaches the neutral point.[1]

Turning to the cases in Series 3, we find the digestion is better than normal. As emaciation is often present in these cases, it must certainly be due to some other cause. It has been claimed that the emaciation in malignant disease (other than in the intestinal canal) is only present when ulceration takes place, and then is probably the result of micro-organisms which elaborate some toxic agent. As none of these was an ulcerative case, this point is negatived. Why the digestion was better than in the normal cases, it is not our present purpose to attempt to explain.

As digestion is impaired in these tuberculous patients, the explanation of the loss of flesh and strength is comparatively simple. Digestion being less, assimilation of food is more difficult. The metabolic activities of the body are altered and the organism has to draw on its own supply of fats, carbohydrates and proteids. In the more chronic cases, the organism has accustomed itself to the altered condition, and so the digestion is better than in the early cases.

1 It has been proposed that if there is a toxin generated by the tubercle bacillus, it may have the direct influence in inciting a greater alkalinity in the tissues, thus making the saliva more alkaline, and, in the same way, decreasing the free HCl of the gastric juice. If this theory be true, the blood also would contain more alkaline salts and therefore be capable of eliminating more products of increased tissue metabolism. Carrying this theory still further, the other tissue cells would suffer as well—the muscles in activity would be less acid and the urine would tend toward the amphoteric point. This theory (which needs decided proof) would thus explain in great part the interference with the metabolic activity throughout the whole body, by showing that the increased alkalinity on the one hand impairs the activity of the digestive fluids and, on the other hand, increases the energy needed for the elimination of waste from the organism.

THE SILVER SALTS IN GONORRHEA.[1]

BY WILLIAM L. BAUM, M.D.,
OF CHICAGO, ILL.;
PROFESSOR OF SKIN AND VENEREAL DISEASES, POST-GRADUATE MEDICAL SCHOOL; FELLOW OF THE CHICAGO ACADEMY OF MEDICINE, ETC.

THERE can be no doubt that the use of the organic silver salts has opened up a new era in the therapeutics of gonorrhea. The fact that solutions of these salts do not coagulate in albumenoid solutions is set forth as one of their chief characteristics, and is claimed to result in the greater penetration of these solutions into the deeper layers of the mucous membrane, thus producing a direct bactericidal action upon the gonococci.

Extensive clinical experience cannot fail to cast some doubt as to the latter contention. In spite of the use of strong injections of these remedies, extending over a considerable period of time, and followed by an apparent cessation of the urethral discharge and absence of gonococci, there are many cases where, after the lapse of two or three weeks, a discharge containing gonococci again appears. This is often the experience in first attacks, where there is no great likelihood of marked organic changes in the mucosa. It might be well to consider the pathology of an uncomplicated gonorrhea.

As Bumm and others (Brewer, in Morrow's "System of Genito-Urinary Diseases," 1893), have pointed out, the gonococci penetrate the epithelial covering of the mucous membrane, and, finding their way through and between the superficial cells, eventually reach the upper stratum of the subepithelial connective tissue. The irritation caused by this invasion results in an acute hyperemia of the part, with dilatation of the capillary vessel and exudation of serum. There is also an increased glandular secretion, with epithelial exfoliation. Later, an abundant transudation of leucocytes takes place from the dilated capillary vessels. These during their outward passage through the epithelial layer absorb and carry with them large numbers of gonococci. When the leucocytes have succeeded in removing the gonococci from the subepithelial tissue, and the gonococci invaded epithelial cells have been washed away, the symptoms begin to subside.

If this is true, then the local treatment of the disease consists in the employment of some method which will induce premature exfoliation of epithelial cells and promote local leucocytosis. This can be accomplished by various methods. The exfoliation of the epithelial layer of the mucous membrane can be increased by (1) the use of irritants; (2) the use of solutions which form albumenoids, such as silver nitrate solutions; (3) the employment of large quantities of fluids, such as the irrigations of weak solutions of potassium permanganate; (4) the employment of fluids, and with them the production of prolonged pressure.

1 Read before the Chicago Academy of Medicine, March 11, 1904.

That the last-named method is of great importance is evidenced by the following experiments. The following solutions were employed for these experiments:

Albargin, gelatose silver, 0.1 to 1 per cent. solution.
Argyrol, 2 per cent. to 10 per cent.
Argonin, casein of silver, 2 to 5 per cent.
Argentamin, 1 to 3 per cent. solution.
Largin, silver protalbin, ¼ to 1½ per cent.
Protargol, proteid of silver, ¼ to 5 per cent.
Picrotol, ¼ to 1½ per cent. solution.
Water.
Saline solutions.
Permanganate solution, 1 to 4,000 to 1 to 500.
Boric acid solution, 1 per cent.

The patient was instructed to use a large piston syringe.

The cases selected for treatment were all first attacks. All of the patients were instructed to first pass water; then to fill up the urethra with the injection, so as to produce tension; to hold in the injected fluid for from three to five minutes; the injection to be repeated five times a day.

Case I.—February 3, 1903. A young clerk, twenty years of age. Duration of discharge, four days. The discharge was profuse and purulent, containing many pus corpuscles, leucocytes, and many colonies of gonococci; not many epithelial cells. He was given a normal salt solution as an injection to be used five times a day. Upon the third day there was still much pain during urination, but the discharge was notably less, contained many leucocytes, many pavement epithelial cells containing gonococci, but few free colonies of gonococci. Upon the tenth day the discharge was mucoid in character, still containing many cells, but less gonococci, and with but few exceptions all imbedded in cells. On account of the pain, I gave him an injection of protargol, one-half of one per cent., followed upon the twentieth day by an astringent solution. The patient made a rather uneventful recovery.

Case II.—February 18, 1903. Laborer, twenty-three years of age. Duration of discharge, three days. Purulent in character. Contained many leucocytes and many free colonies of gonococci. Was given an injection of potassium permanganate, 1 to 2,000, to be used five times a day. The third day showed decided decrease in the discharge, and many epithelial cells, a few red blood corpuscles. Painful micturition. Sixth day, more epithelial cells. Contained gonococci, less pus. Eleventh day, mucoid discharge; few gonococci, mostly cells. Twentieth day, no gonococci. Given astringent injection. Used for two weeks. No return of discharge.

Case III.—March 5, 1903. Traveling salesman, aged twenty-nine years. Duration of discharge, six days. Discharge profuse and purulent; marked swelling of the meatus. Discharge contains much pus and many free colonies of gonococci. Injection; used protargol, one-half of one per cent. Upon the third day, some decrease in the discharge. Strength of injection increased to one and one-half per cent. Few free colonies of gonococci. Many cells containing gonococci. Tenth day, mucoid discharge; many cells containing gonococci. Fourteenth day, still cells; no gonococci. Injection continued to twenty-fourth day. The astringent injection employed for two weeks. No return of the discharge.

Case IV.—March 22, 1903. Dentist, twenty-seven years of age. Duration of discharge, two days. Profuse and purulent. Many gonococci in colonies. Injection; used argonin, two per cent. Third day, decrease in discharge. Fewer colonies of gonococci. Tenth day, discharge slight; many cells containing gonococci. Fifteenth day, few gonococci. Twenty-fourth day, no gonococci. Still some mucoid discharge. Astringent injection used for three weeks longer. No recurrence.

Case V.—March 27. Clerk, aged twenty-three years. Discharge purulent and of four days' duration. Contains gonococci, colonies. Injection; used targin, one-quarter of one per cent. Third day, discharge still profuse, but increase in cells, and strength of injection increased to two per cent. Fifth day, decrease, with fewer colonies of gonococci. Tenth day, discharge slight; many epithelial cells; some containing gonococci. Fifteenth day, still many cells, and few containing gonococci. Twentieth day, discharge ceased. Complains of pain in passing water. Astringent injection for ten days. No return.

Case VI.—May 11, 1903. Grocery clerk, aged nineteen years. Discharge for five days; purulent and profuse; contains many free colonies of gonococci. Injection used, argentamin, one per cent. Third day, passage of water painful; slight decrease in discharge. Injection increased to one and one-half per cent. Seventh day, increase in cells; decrease in free colonies of gonococci. Fourteenth day, slight discharge, containing many cells with gonococci. Twentieth day, mucoid discharge; many cells, and few gonococci. Twenty-eighth day, no discharge. Astringent solution for ten days. No return.

Case VII.—June 5, 1903. Bookkeeper, aged twenty-three years. Discharge for two days; profuse, and painful micturition. Many colonies of gonococci; few cells. Injection; boric acid solution, two per cent. Third day, decided increase in cells, containing gonococci; fewer free colonies. Tenth day, discharge decreased; still many cells containing gonococci. Fifteenth day, discharge slight; still many gonococci in cells. Twenth-fifth day, still gonococci in cells. Thirty-fifth day, no discharge; astringent solution two weeks. No return.

Case VIII.—September 23, 1903. Clerk, aged twenty-eight years. Discharge for three days. Quite profuse. Containing many free colonies of gonococci. Injection of distilled water, colored with methylene blue, 1 to 10,000. Third day, discharge free, but more cells containing gonococci. Tenth day, urination painful; discharge

slight; many cells containing gonococci. Fifteenth day, slight discharge, but still gonococci present. Treatment with water discontinued on account of pain. Argyrol used for two weeks. Subsequently astringent solution for two weeks.

Case IX.—November 16, 1903. Bookkeeper, aged twenty-four years. Discharge for six days; profuse, and purulent, containing many free colonies of gonococci. Urination painful. Argyrol solution, two per cent, used for injections. Third day, pain ceased at once, and discharge slight, containing many cells, gonococci imbedded in some of them. Sixth day, discharge almost ceased; some cells; few of them containing gonococci. Tenth day, no gonococci. Argyrol injection continued to twentieth day, followed for eight days with astringent solution. No recurrence.

Case X.—December 5, 1903. Clerk, aged thirty-one years. Duration of discharge, five days. Purulent and profuse. Many colonies of gonococci; few cells. Picrotol solution, one-quarter of one per cent. used for injection. Caused some pain. Third day, many cells containing gonococci; few free colonies. Sixth day, marked decrease in discharge, mostly cells, few containing gonococci. Tenth day, slight discharge; no gonococci in cells. Fifteenth day, no discharge. Astringent solution used for ten days. No recurrence.

It will be noted that in all these cases the discharge decreased quite rapidly, that its character changed markedly and that the exfoliation of mucous membrane cells where greatest promised the earliest relief. The cases in which the silver salts were employed suffered less in subjective symptoms, and made the best recoveries. Those treated with argyrol were probably the most satisfactory.

I can hardly believe that the organic silver salts owe their beneficial effects to the penetrating power of which so much has been written, but rather to the bactericidal effect produced upon gonococci imbedded in the upper epithelial layer, which is being exfoliated, and in preventing reinfection. From these experiments, I have come to the following conclusions:

1. That solutions of the silver salts, organic or inorganic, do not penetrate the mucosa to any great extent.

2. That the prolonged pressure of any fluid upon the urethral mucosa causes temporary compression of the capillaries; that the removal of this pressure is followed by dilatation of these capillaries, resulting in an increased leucocytosis through the walls of the vessels; that the point of least resistance is the lumen of the urethra; that this induces more rapid exfoliation of mucous membrane cells, and literally carries out the infectious agent.

3. That it is upon the free gonococci thus forced into the surface layer of the mucous membrane that the silver salts exercise this bactericidal action.

URGENT ADENECTOMY DURING THE PROGRESS OF A PNEUMONIA.

BY H. JARECKI, M.D.,
OF NEW YORK;
VISITING OTOLOGIST, HARLEM HOSPITAL; EYE, EAR AND THROAT SURGEON, SYDENHAM HOSPITAL; ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL, ETC.

Lobar pneumonia, while self-limited, is one of the diseases that requires and demands everything that can be done to support the system. In the following instance, during its progress an adenoid operation was performed with marked benefit to the patient.

As pneumonia is characterized by an engorgement of the blood vessels of the parts affected, we can readily understand why venesection was in vogue many years ago. Urgent dyspnea is relieved to-day by means of dry cups. The treatment is one directed toward local depletion. Literature records hundreds of cases of diphtheria in which the process involves the larynx causing laryngeal stenosis and finally the pathological condition invades the lungs and causes pneumonia. The vital indication in a case of stenosis is to intubate, whether pneumonia complicates it or not. For these reasons, to produce local depletion and to relieve an important mechanical obstruction, I did not hesitate to operate.

The record of the case is as follows: I was called by Dr. L. Friedberger to see the patient, Jos. G., aged four months, with the subjoined history.

The child who had been a mouth-breather from birth, had never been seriously ill. He had always taken his nourishment fairly well, although he was never able to drink steadily, being compelled to drop the nipple from time to time. He had now been ill with pneumonia for the past four days with marked dyspnea. The mother complained that the child would not close its mouth to take food or medicine except with extreme difficulty, and, as she knew of the existence of the adenoids, she desired to have them removed immediately.

The family physician explained that the child was practically taking no nourishment by mouth and as the bowels were irritable that direction was out of the question. He thought the symptoms were intensified by the adenoids.

Upon examination, I found a lobar pneumonia, right side, upper one half of lung being involved; temperature 105° F.; respirations, 60; pulse 140. Mouth-breathing marked and child in great distress, undoubtedly increased by the obstruction to nasal respiration. The prognosis was grave, yet the mother insisted upon having the adenoids removed. The risk was carefully explained to her, still she determined to have it done, and earnestly begged as she felt that the child would be relieved.

I consented to operate. With the child held upright in the nurse's arms, I cautiously curetted out the nasopharynx, removing quite a mass of adenoid tissue, using an instrument I had made

for infants. (*New York Med. Journal and Phil. Med. Journal,* Vol. LXXX, No. 7, p. 309).

The child seemed quite exhausted for a few hours, then dozed off at intervals, and twelve hours later began to take a little nourishment.

There was no postoperative treatment; the pneumonia, naturally, was looked after. The next day the temperature was 104° F., pulse 130, respiration 40—and the mother said the child rested much better. The patient gradually improved and on the ninth day the temperature was normal. This is the only case of its kind, that I know of, that has been reported.

115 West One Hundred and Twenty-first Street.

MEDICAL PROGRESS.

SURGERY.

Posterior Gastro-enterostomy.—It is not long ago since one of the leaders of American surgery characterized this as an unnecessarily complicated procedure, and pointed with just pride to a long list of successful anterior gastro-enterostomies. Charles L. Scudder, (*Annals of Surgery,* September, 1904) states that it is coming to be recognized the world over that the nearer to the origin of the jejunum the anastomosis of the stomach is made, the more satisfactory is the convalescence and subsequent course. In Krause's clinic alone, out of many visited by the author was the anterior operation still being used. Kocher's method of doing gastro-duodenostomy is advantageous, because the exit from the stomach is made proxymal to the bile and pancreatic supply. Finney's gastropyloduodenostomy is similarly physiological and each of these procedures is, in the author's opinion, preferable to posterior gastrojejunostomy when possible of application. Scudder's technic is as follows: An ample incision is made through the middle of the belly of the right rectus. This incision must be long. The great omentum and transverse colon are lifted completely out of the abdomen at the upper end of the wound, thus exposing the under surface of the transverse mesocolon. While the left hand grasps the colon, the left fingers push the posterior wall of the stomach in its pyloric portion firmly against the mesocolon and a small incision is made. This incision is enlarged by gentle tearing and should be four or five inches long. The posterior wall of the stomach is picked up by two forceps and the stomach clamp applied. This is placed obliquely upon the stomach so as to avoid the important vessels. The jejunum is similarly picked up and clamped. The anastomosis is so made that the gastric paristalsis corresponds in direction to the enteric. The first or peritoneal suture is taken with curved needle and No. 3 Pagenstecher linen thread. The Cushing suture is used. The curved needle is of such size that it can be conveniently used without a needle holder. The size of the opening which is made by knife and scissors, depends entirely upon the physical conditions. An opening of from 2½ to 3 inches is ordinarily needed. The prolapsed mucous membrane of both the stomach and jejunum is excised. This is done to facilitate subsequent suture and to prevent valve-like obstructions. The postoperative treatment consists in giving small nutrient enemata, one every eight hours for two days. After twenty-four hours liquids are given by mouth and at the end of a week solid foods are allowed. Vicious cycle has not occurred in any of the author's cases. Three questions are as yet unsolved in connection with this operation: (1) the relation between the patency of the pyloris and the permanency of the new opening; (2) the desirability of the permanency, and, (3) the likelihood of an ulcer forming in the jejunum.

Surgical Intervention in Renal Disease.—No branch of surgery has received such tremendous impetus of late years as this. America has been a confessed leader. A. Yvert (*Rev. de Chir.,* September, 1904) in a leading article draws an interesting and striking analogy between the nephrotomy of Pousson and the decapsulation of Edebohls. He divides the subject into three heads, intervention in acute nephritis, in chronic nephritis, and finally in certain essentially medical affections of the kidney itself. The acute conditions which are further subdivided into those arising from ascending infection, those of a circulatory type and those of mixed type, are discussed with admirable clearness and the effect of various treatments indicated. The author seems absolutely just in his treatment of the two opposing theories or technics, as they should more rightly be called, of decapsulation and kidney incision. He traces the steps by which Pousson reached his conclusions as to the efficiency of renal section, and shows to what a degree they resemble the steps by which Edebohls arrived at a very similar conclusion in regard to decapsulation. The review of decapsulation literature up to date is very full. As to the choice between the Pousson or the Edebohls operation, the author says, that in considering the two, the brilliant researches of the English surgeon, Harrison, should not be forgotten. To this early observer the tense capsule of the congested kidney of acute nephritis bore the same relation to that organ as the iris to the eye in cases of glaucoma. Furthermore, in the opinion of the author, although decortication does not appear to present either great technical difficulties or to entail serious postoperative complications, it is, nevertheless, well to recollect, that it constitutes in every case a somewhat more difficult intervention and one certainly more grave in its possible sequels than simple section of the kidneys. A further and even greater objection to decortication would appear to be that its benefits do not begin to show themselves until at the end of eight or ten days at the minimum, whereas, on the other hand Pousson's nephrotomy gives immediate results. Continuing, the author says: "It is essential to remember that the very principle of the technic of decortication has been brought under very severe criticism from a histological standpoint, it having been shown that the supposed increase of vascularity between the parenchyma of the kidney and the perirenal tissue probably exists either to a very small extent or else not at all. The good arising from decapsulation, then, must be attributed to a release of the endonephrytic tension, or else to a stimulation of the reflex renal nervous system." Accordingly, the conclusion is that in the present status, no positive choice can be made between decapsulation and nephrotomy in the treatment of chronic nephritis.

Neurofibroma of Acoustic Nerve.—Even to-day, in the face of the brilliant successes which have attended a great number of attempts to remove cortical brain growths, the proportion in which success is ultimately attained is small. Discouragingly true is this of growths which infiltrate the brain sub-

stance. Fraenkel, Hunt, Woolsey and Elsberg (*Annals of Surgery*, September, 1904) state that in their opinions the so-called acoustic neuromata constitute a group which may properly be considered as favorable for surgical intervention. This would unqualifiedly be true were it not for the deep situation of the growth in the triangular space at the base of the brain. This is formed by the junction of the cerebellum, medulla and pons. The growth under consideration is a neurofibroma springing from the acoustic nerve as it emerges from the junction of the pons and the medulla; hence the most important symptom is referable to a disturbed function of this nerve. Tinnitus aurium, Menieres syndrome and deafness are among these characteristic signs. Inasmuch as the development of the tumor is slow, the integrity of the nerve is usually preserved for a long period. Inasmuch, however, as the pons, the medulla and cerebellum form the margins of the small triangle in which the growth develops, it is not usual that symptoms traceable directly to pressure upon these parts may arise almost coincidentally with evidences of pressure on the nerve. At this stage also the well-known general symptoms of cerebral tumor are usually well developed. The tumors vary in size from a cherry to a bantam's egg. They are covered by a smooth capsule and are nodular. They are loosely attached to the basilar membranes, so that enucleation is readily accomplished. The technic of the operation, as described by Woolsey, is as follows: A large skin flap was turned down so as to expose the lower half of the squamous portion of the occipital bone and the posterior part of the left mastoid. The occipital was bared almost to the foramen magnum. The bone was here trephined and the opening enlarged. Its outer boundary was thus the lateral sinus and its inner the foramen. The dura was opened and the left cerebellar hemisphere bulged considerably. The finger introduced forward and inward beneath this could easily detect the tumor. It felt hard and could be distinguished from the brain. It was removed piece-meal by the finger, as it was too large to take out in toto. This resulted in laceration of the cerebellum. A drain was instituted to prevent blood-clot formation. Three hours after operation, the patient died in collapse, autopsy showing that death was due to hemorrhage within the left middle peduncle of the pons. Elsberg advises operation in two stages. The authors conclude that the acoustic tumor syndrome is well defined and that the diagnosis can be made with practical certainty. The slow and essentially benign nature of the growth and its easy enucleability favor surgical intervention. Its deep situation at the base in immediate proximity to vital centers offers very serious obstacles. Improvement in surgical technic should be made in the direction of avoiding undue concussion in the removal of bone, in perfecting a method of extirpation of the tumor by which it could be removed without injury to the surrounding parts and, lastly, division of the operation into stages.

Acute Intestinal Obstruction.—No phase of any pathological condition is more apt to be fatal in its consequences than acute intestinal obstruction and certainly none calls for more active and intelligent treatment. Arthur E. Barker (*Lancet*, September 17, 1904) defines the factors in obstruction, which have to be treated surgically, as follows: (1) There are mechanical or anatomical factors; (2) physical factors, and third, vital factors. The first consideration very naturally demands the most immediate action and thorough technic. The position of the obstruction is a point of well-known importance. By "physical changes" the author includes the anemia and the venous engorgement of the different parts as well as the consequent edema, thrombosis and ulceration, one or all of which may follow intestinal obstruction. By "vital changes" he states that he refers to the most important factor of all. It may, as he says, be easy to mechanically relieve the cause of obstruction, but unfortunately, by the time the patient has reached the surgeon such changes have taken place that this does not suffice. There are swarms of bacteria and fecal material being constantly retrogated to the site of obstruction peristalsis. Great quantities of toxins are made, for which there is no escape save by absorption into the general system. Nor are the toxins alone in their migrations, for the depressed condition of the patient so enfeebles the reactionary powers of the serum and other protective agents, that bacteria themselves, migrating under these auspicious conditions to distant parts and setting up characteristic changes in them, often constitute the most serious type of vital change. The conclusions of this interesting article are as follows: (1) That hitherto too much stress has been laid upon the mere removal of the mechanical stoppage and not enough upon the evacuation of the putrid material, which is killing the patient; (2) that the older method of emptying the bowel by establishing an artificial anus is unsatisfactory, as the bowel is in a state of paresis or complete paralysis and only expels its contents very slowly and until it is cleaned out, the cause of the paralysis remains in great part. Any careful analysis of a long series of cases, probably in all that are still within the reach of any operative procedure, is to resect the tract of paralyzed and distended bowel at once. This would not, of course, apply to recent cases where the bowel is not seriously damaged by the retained feces and is manifestly sound at and above the seat of observation. But excluding these, there remains unfortunately a large group of cases where one is face to face with a disastrous state of things which requires very bold action. This free resection of the gut, which is viable, but in which sufficient change has taken place to paralyze its muscular activity, implies a wide and far-reaching departure from the usual course. It is well known that paresis is one of the most difficult conditions to treat when the intestine is seriously affected. It may, however, be that it is as desirable to resect palsied gut as to remove that which is dead. The after-treatmetn of these cases the author considers to be of extreme importance, and it is as revolutionary as his technic. He invariably sits them up in bed, often from the first day. Hitherto he believed that too little food had been given by the mouth. If in small quantities and of an easily digestible nature, it may be given safely with a greater degree of freedom than usually believed. This is particularly true of those cases in which the diseased bowel has been resected. The diarrhea, which often subvenes in these cases, is often troublesome, but since it represents nature's efforts to free the body from putrid material, it is not wise to check it too early. He advises large and continuous doses of carbonate of bismuth.

Appendicitis Complicated by Duodenogastric Ulceration.—Although the pathological conditions which lead to the condition are unknown, it is a well-recognized fact that ulceration of the stomach and of the duodenum is prone to be provoked, or, at any rate brought into activity by operation for the relief of other conditions. H. A. LEDYARD and R. E. SEDGWICK (*Lancet*, September 10, 1904,) report a post-mortem finding on an appendectomy case as follows: On the pancreatic surface of the duodenum was a large ulcer, the base of which was formed by pancreatic substance, in the midst of which opened two vessels of the third degree. There has been nothing unusual in the history of this appendectomy, except that hemorrhage from the bowels began about three days after operation and continued for twenty days. Rodman has suggested as a cause for this a septic thrombus in the omental vessels, and in support of this, it is noteworthy that in the case recorded the great omentum was adherent to the abdominal wall. The authors report a second case of a similar nature.

PATHOLOGY AND BACTERIOLOGY.

Arteriosclerosis in Nephritis.—In order to determine if arterial changes are always concomitant with intestinal nephritis, P. PRYM (*Virchow's Archiv*, Vol. 177, No. 3) examined the vessels of two young individuals who had died of Bright's disease, and who had not exhibited any clinical symptoms of arterial change during life. In both cases severe lesions were encountered in the smaller branches, most markedly in the afferent vessels of the kidneys, the intima was distinctly hyperplastic and fatty degeneration was very evident. It is probable that genuine morbus Brightii without beginning arteriosclerosis does not exist.

Syphilitic Aortitis.—D. FAHR (*Virchow's Archiv*, Vol. 177, No. 3) has often observed inflammatory changes in the aorta which manifest themselves as small infiltrations around the vasa vasorum of the adventitia. This infiltration may extend to the media and may become so intense that portions of the media are destroyed completely. The etiology of this process is very frequently syphilis, but it must not be forgotten that alcoholism and certain infectious diseases may be responsible for exactly the same lesions. Hence syphilis can never be diagnosed absolutely from the condition of the vessels, but if the granulation tissue of the media changes into connective tissue, which has a tendency to form a deep, retracting scar which manifests itself microscopically as a puckered depression, the case is very suspicious. Even extensive inflammatory changes alone in adventitia and media will not enable a diagnosis.

Fibrinous Coagula upon Placental Surface of Chorion.—Chorionic villi are generally covered by two layers, a cellular layer consisting of the cells of Langhans and a syncytial layer of nucleated protoplasma, without differentiation into cells. Where the syncytium clothes the villi the chorionic surface shows numerous capillaries; where it is absent and in its place a layer of fibrin is found, the capillaries are very scarce. The presence of the syncytiums is therefore dependent upon the existence of a capillary network in the opposite fetal connective tissue. Both disappear completely during the second half of pregnancy, and the syncytium is replaced by fibrin. Syncytium and fetal capillaries thus belong together, and the exchange of food and waste material between mother and the epithelial layer of the fetus is probably carried on by the syncytium. J. BILAND (*Virchow's Archiv*, Vol. 177, No. 3) states that the fibrin is derived from the maternal blood. The syncytium normally prevents coagulation, but when this disappears the blood will come in contact with the cellular layer which directly favors clotting, owing to the presence of a special enzyme. The cells will finally undergo coagulation necrosis and disappear. Later on the fibrin will lose its property of staining with specific stains, and will become canalized, owing to the activity of leucocytes.

Cirrhosis of the Liver from a New Standpoint.—In examining a large number of stomachs at autopsy, F. BLEICHRÖDER (*Virchow's Archiv*, Vol. 177, No. 3) was struck by the close resemblance of the gastric lesions of cirrhosis of the liver and with those of blood diseases, such as pernicious anemia and leucemia. In following up the subject, the author found a number of other points of resemblance. Thus, a marked anemia is often present in cirrhosis, and the red cells do not form rouleaux. Both cirrhosis and leucemia are often accompanied by ascites, and the splenic tumor in the former disease is certainly not due alone to stasis of the portal blood, for it is often well marked before other signs of portal obstruction are present. Furthermore, the spleen is much softer than it would be in simple congestion, and the veins contain many lymphocytes. An important point is the usual occurrence of red bone-marrow in cirrhosis, where normally yellow marrow exists. There is little evidence to assume that cirrhosis is a primary disease of the liver cells, for even in advanced cases their functions are preserved, that is, bile and urea are still formed, and the carbohydrate mechanism is not interfered with. It is much more rational to assume that cirrhosis belongs to the class of blood diseases, and that the characteristic lesions are due to the transport of lymphocytes from the spleen. These cells then migrate through the vessel walls, collect around the portal veins in the liver, and are finally converted into connective tissue. The same process, to a lesser extent, is seen in many acute infectious diseases where a hyperplasia of the spleen exists, and some of the lymphocytes are carried into the liver. The different forms of cirrhosis described are probably analogous in their origin, and transition forms occur frequently. The connective tissue is never pure, but is always mixed with round cells, a small number of which persist even in advanced stages. Variations in size and appearance of the liver do not depend upon different forms of inflammation, but merely upon the eventual distribution of the connective tissue. If jaundice occurs it is not obstructive in nature, since the gall-bladder always contains bile, and the passages are patent. It must be explained by the disintegration of red blood cells so common with all blood diseases, and has thus the same origin as the pigmentation, the deposit of iron in many organs, the anemia and the increased excretion of urobilin so frequently found in cirrhosis. Other organs may also participate in the hyperplasia, such as the kidneys, and where diabetes also exists, the pancreas. The process in these organs is precisely the same as that in the liver. Banti's disease should not be looked upon as a disease by itself, but merely as a form of cirrhosis. The proper therapy of cirrhosis is by arsenic, iron and quinine just as in anemia.

CAUGHT RED-HANDED.

From time to time the Medical News has called editorial attention to the widespread and flagrant custom of drug substitution carried on by many retail pharmacists in this and other cities.

In many of these instances, as we have pointed out, the druggist has been the victim, at times innocent, at times apparently not unwilling, to the commercial argument of "something just as good," at a greatly reduced rate.

As intimated, this has been going on for a number of years, particularly for the proprietary remedies, but it has only been since the introduction of the modern synthetic analgesics and antiseptics that the rascally substitutors have enlarged their sphere of activities and practically preempted the market in this class of goods.

Heretofore all attempts to put a stop even to the more flagrant types of this traffic have been abortive, but we are pleased to learn that through the activities of some of the more sinned-against foreign drug houses a wholesale roundup of the counterfeiters has been successfully brought about, and we look for a proper treatment by the courts of these most malevolent criminals.

A brief glance at the list of the remedies which were actually found in process of manufacture, with false labels, false contents and improper directions, shows that many of our most trustworthy drugs are among them. Trional, aspirin, lactophenin, chloralamid, salol, phenacetin, salipyrine, sulphonal, urotropin, aristol, and a number of others, equally important remedies, were among those counterfeited.

While not oblivious to the importance of the great commercial loss that must result to the legitimate manufacturers from such wholesale substitutions, the widespread injury that results to the public is, we believe, of far greater importance.

Such a traffic, if permitted to continue, works devastation in many directions. It undermines the confidence of the patient in his physician, to the detriment of his patient's health, the physician is deterred from using well-established remedies, and in many instances substitution will actually cause death in patients who are seriously ill. It does not need great acumen to foretell that a dose of sulphonal given to quiet a patient ill with pneumonia, may cause death if over 80 per cent. of it is the impure and highly poisonous acetanilid; and this is one example only.

It is a matter for true congratulation if this murderous traffic can be stopped. We commend to the attention of the District Attorney the leaders of this gang of substitutors, and offer our hearty wish that they be prosecuted to the full extent of the law. Premeditated attempt to murder is a justifiable charge.

THE HEART AND AORTA IN CONGENITAL SYPHILITICS.

As investigations on syphilis multiply, it is becoming more and more certain that this disease spares no anatomical system of the body. Besides the vulgar lesions of the bones, skin and viscera, one knows that the nervous centers may be directly or indirectly attacked, as in tabes or general paralysis. Degny (Thesis, Paris, 1903) has shown by a large number of documents, that the circulatory apparatus is also involved in syphilis.

Numerous are now the instances where syphilis has produced myocarditis, cardiac sclerosis, endocarditis, and pericarditis, while Degny's study of aortitis and aortic aneurism shows that in about 50 per cent. the affections have a syphilitic origin. This authority has also described cardio-aortic syphilis, to which particular attention should be given. In point of fact, it can be shown that congenital syphilis may attack the cardio-aortic apparatus in three different ways, namely: (1) By producing syphilitic lesions in the myo-

cardium, just as is observed in the adult; (2) by favoring degenerations which are by no means syphilitic in nature, but whose primary cause appears to be due to the presence of the syphilitic virus, and (3) dystrophic lesions especially attacking the development of the heart and its valves.

Clinically, the latter group is by far the most important, and here may be included more particularly mitral stenosis, whose nature has so often been discussed, and which has usually been considered a lesion of hereditary tuberculosis. Degny relates several cases where the cardiac lesions coincided with various malformations, indicating in a most evident manner, a particular state of degeneration. As has been pointed out by Rendu, in these subjects the condition is more one of degeneration than of syphilitic manifestations in an active state.

In the second group one includes certain changes in the cardiac muscle fibers which are not specific, but which are found in cases of congenital syphilis. And, lastly, in the first group gummata of the myocardium and arteritis in various forms are found.

Houchard believes that there is reason to question whether or not congenital syphilis is not responsible for the production of aneurism more frequently than has generally been admitted. The question is still undecided, but he nevertheless thinks that it has been answered in the affirmative because no small number of cases of aortitis met with in young subjects or adults, as well as aortic and cerebral aneurisms, having no evident cause, are in reality the products of congenital syphilis.

It may be said that besides those lesions of syphilitic nature such as gummata, aortitis, endocarditis and myocarditis, all other lesions observed are parasyphilitic, and, in their production, several important factors enter into play.

In the first place, in nearly all cases one should incriminate a defect in nutrition, an organic loss of power in the newly-born syphilitic, whose development, from this very fact, is hindered, and who, still more, is placed in a most excellent condition of receptivity for secondary infections.

In point of fact, if clinically, under certain circumstances, and in the adult particularly, syphilis appears to be, or really is, indifferent to certain infections, as pneumonia for example, and although it does not appear to aggravate or favor their development, in the child, on the contrary, syphilitic weakness favors chronic infections. These children easily develop gastro-enteritis, athrepsia, purulent otitis, syphilitic coryza, and bronchitis.

Thus all the doors are thrown open for the reception of infection, for the production of a subacute or latent chronic endocarditis, and these in their turn are important aids for weakening the noble elements of the organism. These phenomena may easily transpire in intra-uterine life, and thus may be conceived the multiple parasyphilitic lesions that are sometimes observed at birth. Consequently, specific or superadded lesions, mechanical disturbances and general dystrophy are the principal causes presiding over the evolution of the congenital syphilitic cardiopathies.

The reason why this subject has been insufficiently studied and described is the great difficulty in making a diagnosis. The syphilitic infection may be unknown to the mother, while the infant may not present the specific cutaneous lesions, but, nevertheless, he is a congenital syphilitic, for he has contracted the disease from his father.

ECHOES AND NEWS.

NEW YORK.

New York Academy of Medicine.—There will be a meeting of the Section on Medicine on Tuesday evening, October 18, at 8:15 o'clock. Here is the interesting program: (I.) Presentation of Cases and Specimens. (II.) Clinical Reports: "Two Cases of Duodenal Ulcer with Operation," by W. L. Baner, M.D. (III.) Paper: "The Malarial Types of Infective Endocarditis," by Warren Coleman, M.D. (IV.) Paper: "The Present Status of the Clinical Value of Laboratory Tests as an Aid to the Practitioner," by John S. Thacher, M.D.

Eastern Medical Society.—The Section on Pediatrics of the Eastern Medical Society will meet on Thursday, October 20, at 8:30 P.M., at Clinton Hall, 151-153 Clinton Street. The papers of the evening will be: "Pathology of Emypema," by Edward Schnaper, M.D.; "A Résumé of 175 Cases of Empyema, Clinical Features, Prognosis and Treatment," by Henry Koplik, M.D. Discussion by Drs. Louis Fischer, Francis Huber, F. N. Wilson, A. E. Isaacs, J. Barsky, I. S. Hirsch, and others. There will also be a presentation of cases and new instruments.

Dr. Clifford Allbutt, Honorary Member of Academy.—At the close of the scientific meeting of the Academy on Thursday, October 6, President Andrew H. Smith introduced Dr. Thomas Clifford Allbutt, Regius Professor of Physic in the University of Cambridge, as an Honorary Member of the Academy.

Gifts for P. & S.—Among the gifts to Columbia University, announced during the past week, are $225,000 from Mr. and Mrs. W. D. Sloane for the Sloane Maternity Hospital and $60,000 from H. W. Carpentier, to endow a chair in the Medical Department.

St. Luke's Hospital, Utica.—St. Luke's Hospital in the city of Utica, which for the past twenty years

has been a successfully managed private hospital of fifty beds, is to have a new building on a new and better site, the gift of Mr. and Mrs. Frederick T. Proctor, of Utica. The new building, which is now nearing completion, is to have eighty beds, and is a fireproof structure of brick, stone and steel, of the most modern approved type. The entire expense of the building and furnishing is borne by this one family, and the structure completed is to be turned over to the present Board of Trustees of St. Luke's Home and Hospital. This is the largest single gift that has ever been made for philanthropic and charitable purposes in this part of the State.

PHILADELPHIA.

Medico-Chirurgical College.—Dr. William Pickett has been elected Professor of Mental and Nervous Diseases, to succeed the late Dr. F. Savary Pearce. Dr. Pickett has for several years held various responsible positions in connection with the Insane Department of the Philadelphia Hospital and is one of the most prominent of the younger neurologists of this city.

Bequest for Alma Mater.—By the will of Dr. Spencer Morris, of the class of 1871, the University of Pennsylvania receives $10,000, the income of which, to be known as the "Dr. Spencer Morris Prize," is to be awarded yearly to the person passing the best examination for the degree of doctor of medicine.

Lectures on Tropical Medicine.—The course of lectures on Tropical Medicine at the Jefferson Medical College is being delivered this year by Major Walter W. McCaw, M.D., U.S.A. The course consists of ten lectures. They are given Monday afternoons at 4 P.M., in the hospital amphitheater, beginning October 3.

Woman's Hospital Widens Scope.—The Women's Homeopathic Hospital at Twentieth Street and Susquehanna Avenue is to erect an additional building to be used as a man's ward. It has been run strictly as a woman's hospital for twenty years.

Parents May Visit Municipal Hospital.—In the future parents who have children under treatment in the Municipal Hospital, for any disease except smallpox, may visit them if they so desire. They will be furnished with protective suits by the city. Both phones have been installed in all the wards in order that information regarding patients may be obtained direct.

To Shorten Time of Keeping Milk.—Efforts are being made to shorten the time milk is kept before being delivered to the consumer. The idea of Director Martin is to have milk trains run late at night instead of early in the morning, thus obviating the necessity of keeping milk until the following morning as so often done at present. He says: "It is our effort to have an inspector meet every milk train and his inspection takes time. If it is not completed early enough to permit the serving of milk for breakfast, when most consumers desire it, the milk must be kept over until the next day. If the trains would come in late at night the inspectors can complete their work and release the milk in ample time for early morning distribution. The large wholesale dealers have been interested and they approve of the contemplated change. The railroads have promised to do all they can to assist."

Typhoid Epidemics in Pennsylvania.—Typhoid epidemics are in progress at West Chester and Pitcairn. There are from thirty to forty cases in the former town. A committee of physicians endorsed the action of the Board of Health in stopping a certain dairyman from serving milk. In Pitcairn there are fifty cases in a population of 3,000. As the result of inspection of the water supply by the State Board of Health, several dairies whose herds are supplied by springs containing bacteria have ceased their supply.

Report of Norristown Asylum.—The annual report of the male department of the State Hospital for the Insane at Norristown shows that of 1,175 patients on the rolls, 83 are on parole. Of these, 17 are employed as attendants in the various wards and in the refectory. Admissions for the last year were 216. Seventy-six patients were discharged restored, ten improved and three unimproved. There were 78 deaths during the year, a rate of 5.8 per cent. This is the lowest death-rate in fifteen years.

CHICAGO.

Campaign in Behalf of Tuberculous Patients.—Medical organizations of the State are planning a campaign of education and publicity for the purpose of arousing the public to the fact that a great part of the thousands of lives annually lost in Illinois through tuberculosis can be saved if the afflicted ones are sent in time to isolation camps, similar to the one established near Ottawa, Illinois. To secure the establishment and maintainance of such camps by the State is another purpose for which the movement has been started. Some of the most prominent physicians of Chicago and other cities and towns of the State, without regard to school of practice, have been chosen to organize a "Committee of Promotion" from citizens not members of the medical profession, which is expected to solicit and administer the funds needed for the campaign of education. A circular letter has been issued by the Illinois State Medical Society, the Illinois State Hoemopathic Society, and the Illinois State Eclectic Society, jointly, setting forth the purposes of the crusade and asking citizens to join in the work of promoting the movement. In this circular it is stated that seven thousand persons died of pulmonary tuberculosis in Illinois in 1903, and about half that number in Chicago alone. This means an annual loss to the State of $36,000,000, to say nothing of the attendant suffering and sorrow. The camp at Ottawa, under the administration of Dr. J. W. Pettit, of that city, is run on as nearly a self-supporting basis as possible, all medical services being gratuitous. In furtherance of the movement the circular states that the physicians of the State are ready to furnish newspaper articles, lectures before Chautauqua assemblies, teachers' institutes and other gatherings, and to render any other services that may be required of them in the cause without pay beyond the traveling and hotel expenses of the lecturers.

The Use of Bisulphide of Carbon in the Treatment of Tuberculosis.—Professor Coramilas, of Athens, Greece, read a paper with this title before the Chicago Medical Society, October 5. He gave an epitome of his work from 1891 up to the present time with the use of this agent. After detailing numerous experiments on animals with the bisulphide of carbon, and presenting a report of 64 cases, the author drew the following conclusions: (1) Bisulphide of carbon has no disagreeable effects; (2) it has a strong action against tubercle bacilli; (3) by its action as a parasiticide, antizymotic, antiseptic, dissolving, and penetrating all tissues, it cures tuberculosis; (4) it should not remain in obscurity, but take its place in therapeutics as a valuable remedy.

Some Common Errors in the Treatment of Pulmonary Tuberculosis.—Dr. Norman Bridge, in a paper with this title, read at the same meeting, said that the current methods in the treatment of the pul-

monary form of tuberculosis averaged better than those of old. Results showed this fact. The mortality of tuberculosis had been reduced in less than three decades by probably 29 per cent. of the former figure, or from 14.25 to 10 per cent. of all deaths. These results were not accidental, but were clearly due more to the better management of the pulmonary form than to any other influence. He said it was somewhat easier for the practitioner to think that quinine or cod-liver oil, or creosote, or a change of climate, some inhalations of drugs or a so-called antitoxin, was good for tuberculosis, than it was to understand that the great first purpose of all treatment was to increase the physiological power of the patient to resist the disease and destroy or circumscribe its course within his own body. With all our study and experimentation, and notwithstanding all our theories and hopes, this truth stood as the one cardinal postulate of the subject up to the present moment. Our greatest and most common error had been against this truth, and the results had been correspondingly sad. To give creosote to the extent of lowering the digestive power, or to give serum injections to the production of phlegmons and higher temperature, or to give coal-tar drugs for fever, while the patient was allowed to go on in his usually unhygienic course of life without advice of correction, was an error so awful in its results that not even confession and penance were sufficient atonement. And all practitioners had sinned in some of these directions, and some of them grievously. Every patient should be constantly supplied with outdoor atmosphere in such abundance that every successive inspiration brought a fresh dose of air to the lungs and none from previous expirations. Every one should have long hours of rest; if feverish, the rest recumbent should be almost or quite constant, for exercise increases the fever. The digestive powers should be made to do their best under the most careful supervision and direction toward improving the nutrition and possibly also the resisting power of the patient. Practitioners have believed the patients who say they could not eat because they had no appetite, forgetting that a patient could usually be led to take the right food as well as to take medicine. Practitioners have agreed with the patient's theory that an appetite is necessary, and that food must be adjusted to the appetite; whereas, the truth was that in tuberculosis the food ought to be adjusted to the patient, and the appetite to be ignored almost completely. A tuberculous patient was never helped to resist the disease by muscular development above his normal standard. A consumptive's body should always be well and equably clothed, and never be hampered or restricted by garments. Snug corsets and conventional gowns were an abomination for the tuberculous woman. Worn as they were by most such women, they frequently tipped the scales in favor of death rather than recovery. Pulmonary tuberculosis was a *long* disease, and required a long and steady course of the best hygiene an management to ensure final and lasting recovery. Climatic treatment of tuberculosis had rightly become popular the world over; yet he was compelled to the belief from abundant observation that of all the remedies prescribed for the tuberculous, one of the most unfortunate and unsatisfactory was climate as it was usually employed. Going away for climate was one of the most abused and misused of all the great measures for the sick; and so what ought to be a blessing unspeakable often became a pitiful deception and a vision of death. This misfortune was largely an error of the people, but the profession was greatly at fault about it also. In more than half of the instances where it was advised it was for the wrong kind of cases, or at the wrong time, or for the wrong people; that is, with poor regard for all the circumstances in the situation. The author mentioned a list of faults of climatic treatment. Finally, the surest proof of skill and usefulness of a physician was his capacity to turn to the benefit of the sick the simple and homely facilities that were all about them. The best results with the fewest tools was the test; and no more inviting task was ever offered to physicians than to bring to the thousands of tuberculous victims, who were unable to go properly to the better climates, and at or near their homes, the benefits of the modern treatment of this disease. And it could be done, either in their own houses or in home sanatoria, and done superbly in a large proportion of cases. If it were done, it would reduce the mortality another ten per cent., and it would be done, for the twentieth century internist was capable of it, and he must not fail.

GENERAL.

Congress of Military Surgeons.—The International Congress of Military Surgeons convened at the World's Fair Grounds with a large attendance. The congress is held in lieu of the thirteenth annual meeting of the Association of Military Surgeons of the United States and will continue during the week. It is presided over by Medical Director John Cropper Wise, of the United States Navy, assisted by Major James Evelyn Pilcher, of the United States navy. The objects of the Congress are to cultivate and maintain an international community of interest by which the services to the sick and wounded in war may be equalized, elaborated, and perfected throughout the world.

Psychoses Among Soldiers.—The hardships and bad food, as well as the nervous tension caused by the ever-present danger, all predispose the soldier in the field to nervous derangements and insanity, says the *Globe*. Russian physicians report that in the wars with both Turkey and China a large number of acute psychoses were met with, and many men who had gone mad were shot that they might not fall into the hands of Chinese torturers. During the present war, says the *British Medical Journal*, many cases of delirium have been observed in the garrison at Port Arthur. On board the Manchuria, when taken by the Japanese, were found fourteen insane soldiers.

New Hampshire Legal Civilization.—The legality of the practice of Christian Science in New Hampshire was upheld by the Supreme Court of the State. In substance the court holds that the practice of Christian Science is legal and that patients who have resorted to such treatment cannot recover any damages in case the practitioner uses the accepted Christian Science methods of treatment. It decides that Christian Science treatment is neither negligent nor deceitful, and that, as Mrs. Speed went to Mr. Tomlinson seeking Christian Science treatment, it was his duty to treat her by that method, and that she could not claim that such method of treatment was contrary to public policy.

Some Theories of Seasickness.—A French physicist, Professor M. R. Bonnin contributed an article to *La Nature* on "The Mechanical Theory of Seasickness," which was printed in that journal in its issue of September 10. He attacks the problem entirely from the physical side and tells us that when a body is swinging in space it has three forces acting upon it: (1) its own weight pulling it directly downward; (2) the centrifugal action which pulls it away from the pivot point; and (3) its inertia acting in the direction of its own motion. Considering a man on the

deck of a rolling ship as the swinging body "all of his internal organs suspended in the thorax and abdominal cavity tend to oscillate continually becoming relatively displaced from constant traction on their attachments. At certain moments the organs seem to rise, at others they appear to grow heavier, hence an effect of distress which may bring on nausea. Thus we see why the horizontal position which gives a point of rest to these organs in their receptacles, may, up to a certain point, diminish the effects of seasickness."

Looked at in the light of pure theory, Prof. Bonnin's idea certainly possesses the delightful and refreshing elements of ingenuity, but it is a theory and nothing more. It is, moreover, not a good scientific theory, for it fails to explain all of the facts in the case. Reasoning by analogy is always a dangerous process and never more so than when one is trying to explain a scientific fact. The relationship between a swaying pendulum observed on land and the swaying body of a man on a rolling ship is surely remote enough, and one wonders at the boldness of the conception. There is to be sure no exact proof of the etiology of *mal de mer* but were there one it would most likely come from the domain of experimental physiology rather than from the realms of pure mathematics. Has this good man never heard of the probable function of the semicircular canal in controlling, in part at least, the equilibrium of the body? If so he makes no mention of the fact. Dizziness and nausea are sometimes caused by irritation of the nerves of common sensation, though the relation of visceral sensations to equilibrium is very little known.. It is known, however, that interference with certain cerebral functions is a potent cause of nausea and vomiting and upon this fact depends the exhibition of several of the commoner drugs used as emetics. Professor Bonnin evidently considers seasickness a condition due to direct reflex from the stomach, and may it not be a psychical condition as well dependent upon the stimulation of the central ends of the vagus? Nothing is known concerning the communication of the vagi with the organs of hearing, yet variations of pressure on the endolymph might well account for a number of inexplicable sensory conditions. Moreover, seasickness is commonly preceded by giddiness and headache, which also point to the central origin of the affection. James has shown that among deaf-mutes, in which the internal ear was defective, rapid rotation in a swing failed to produce any untoward symptoms. Whether seasickness is dependent upon muscular, tactile, aural or visual senses, or upon all of these together, may remain unknown for many years to come, but its occurrence must be a very certain quantity for thousands of people who are willing to brave the wrath of Neptune in order to become acquainted with countries and nations lying beyond the seas.

Hygiene Congress.—The first International Congress for the Hygiene of Dwelling Houses and Homes has been called at the instigation of the French Hygienic Society, to meet in Paris on October 15 to 20. The premier, M. Combes, has accepted the honorary presidency, and specialities will discuss the various phases of domestic hygiene in six sections. The questions for one section are as to the proper construction of a city house, the garden, and the yard, the arrangements for proper supply of air and for winter heating, the disposal of garbage, and the like. Another section will discuss the same question in reference to country homes; a third will discuss the tenement problem; another schools, etc. The discussions are to be published, and a special house hygienic exhibition will be arranged in connection with the congress. There is already a general International Hygienic Exposition in Paris, running from August to the end of November.

Physicians in Russia.—While Germany has an overproduction of physicians, the reports of the Russian Ministry of the Interior complain of unusual dearth in that country, writes the *Evening Post*. The St. Petersburg *Medical Weekly* states that at present there are 21,827 physicians in Russia, of whom 21,090 are men and 757 are women. Of these European Russia has 19,188. Naturally, the cities are best supplied—St. Petersburg with 2,272; Moscow with 1,528; Warsaw with 1,043; Kiev with 689; Odessa with 613. In the Caucasus provinces there are 1,224; and in the possessions in Central Asia 459. The whole vast Siberia reports only 788. In southern European Russia there are districts where there is no physician for 100 versts around. The reason assigned for this paucity is the poor pay received, physicians being called only in the gravest cases, and many of the common people preferring the services of quacks and superstitious priests. The Military Department complains bitterly that it cannot secure a sufficient number of surgeons for the war. Rather singularly, a decrease in the number of medical students is reported from England also; the number in 1891 having been 2,405 for the United Kingdom, while the latest total enrollment is only 1,538. It will be recollected that Austria recently reported a similar state of affairs.

Extermination of Mosquitoes.—At the meeting of the State and Provincial Boards of Health of North America, held in Washington, D. C., last June, there was a discussion in regard to the extermination of mosquitoes, an official report of which has only just been issued. The following resolutions was adopted:

"Whereas, It has been established that the diseases of malaria and yellow fever are transmissible by mosquitoes of certain species; therefore, be it

"Resolved, That it is the duty of State boards of health to obtain such legislation and appropriations as may be necessary to secure drainage of swamp lands, and to treat the surface of shallow ponds and pools with such substances as are recognized as being destructive to the life of mosquitoes of all species."

Dr. L. O. Howard, chief entomologist of the United States Department of Agriculture, read a paper prepared by Henry Clay Weeks, of Bayside, L. I., secretary of the National Mosquito Extermination Society. This included the following statements: "Entomologists have disproved one of the most persistent mosquito fallacies—that mosquitoes may breed without water. This romance is heard from educated persons almost daily. Entomologists also have shown the efficiency and the rationale of oil as an exterminator. It falls upon those who state that there are other means of contracting malaria and yellow fever than by the bite of an inoculated mosquito to prove their case. The reverse has been most clearly shown. We may and should always maintain, too, that these actual diseases are not, by far, the only health reasons why mosquitoes should not be tolerated. There are, besides, the nervous irrigation, the disturbance of much-needed rest, and others of the less palpable cause of ill-health. Given, then, the certain proof we have of this menace and positive knowledge of the scientific means at our hand for its elimination, there would seem to be but one course, which should be immediately adopted and vigorously carried out, and that is, to get rid of the known conditions which cause the trouble, viz., standing water in every form—or else make

such water perfectly safe, as may be done by larvicides, or, if that may not be, by the installation of fishes. The main reliance should be drainage. It is about six years since the writer urged in the press first, the importance of drainage, as results had shown that drainage for commercial purposes had eliminated the pests; and from a close intimacy with such work since the idea has been positively established. A practical illustration of the need and results of anti-mosquito work may have escaped your notice. It is given in the *Comptes Rendus* of the Paris Academy of Sciences, and refers to the town of Ismailia, on the Suez Canal. Here formerly it was healthy. There were no mosquitoes. Suddenly they appeared, probably from conveyances of travel, and became unendurable. Between 1897 and 1902 there were 2,000 cases a year of malaria. Relief work was planned, and in one year, 1903, it reduced the cases to 200.

The Drug Frauds.—The only cause, writes the *Times*, for surprise in connection with the detection and arrest of the gang of swindlers and counterfeiters engaged in the manufacture and sale of faked drugs and pharmaceutical preparations is that it has taken so long to catch those pursuing this nefarious business. It would seem as if with ordinary detective intelligence this might have been accomplished long ago. To locate the lessee of a postoffice box should not be difficult, not should it have taken years to trace to their source circulars sent out by the thousand with a return address and a place of payment for C. O. D. orders. However, this is beside the fact. The question of police efficiency is not at the moment under consideration. The disquieting fact in connection with this startling revelation of a kind of crime which may determine the issue of life or death is not that unprincipled men should be very glad to make a dishonest profit in this way, and if the profit was large enough to incur the risk of State prison in connection with it. But the business of faking drugs is possible only with the guilty knowledge and cooperation of the druggists, wholesale, jobbing, and retail, who have bought and distributed the worthless or pernicious stuff, and who cannot plead innocence of wrong intent so plausibly as to deceive any one of ordinary intelligence. The only chance the fakir had of securing trade was to offer the false preparations at prices below those charged by persons handling them legitimately as manufacturers or agents. The druggist to whom such goods are offered at prices attractively cheap knew either that they were stolen or that they were not what they purported to be. To buy them under either assumption is to make himself deliberately particeps criminis. He might assume that they were "just as good" as the articles they imitated; but, inasmuch, as he could not know this, and was warranted in believing that it could not be true, since there would be only a narrow and unsatisfactory margin of profit in making a cheap imitation as good as the more expensive original, the druggist who has thus supplied himself and dispensed the false preparations on prescriptions is morally guilty of a crime much more serious than that of the commercial fraud of adulteration. It will do some good, of course, to detect and arrest the swindlers who supply these harmful because dangerous, or equally harmful because inert, cheap imitations of expensive pharmaceutical preparations. But it will not reach the root of the evil. As long as those who sell drugs are willing to buy these evidently dishonest imitations and vend them as the goods they imitate, there will be scroundrels ready and willing to manufacture them, just as there will be counterfeiters as long as there are persons willing to buy "green goods" or false coins. It would seem as if it were possible to begin reform in the drug trade from within—but this has seemed possible for so long that one may well despair of living long enough to see even the desire for it find expression in the discussions and resolutions of the associations which represent the business. Perhaps the physicians could assist the good work by a sufficiently emphatic expression of their views on the subject of substitution and imitation.

OBITUARY.

Dr. Joseph N. Henry, U. S. Army, died suddenly October 3 at Devon, Penn. Dr. Henry was Brigade Surgeon in the Philippines for several years and expected to return to his post after some time spent in recuperation. His body was sent to Annapolis and buried with military honors.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, October 1.

LADY CURZON'S PHYSICIANS—NIELS FINSEN AND THE LIGHT TREATMENT—A FRENCH MEDICAL PILGRIMAGE TO LONDON—THE PASSING OF THE EYEGLASS—A VICTIM OF CHRISTIAN SCIENCE.

The British public is watching with the keenest interest and sympathy the struggle between the powers of life and death, now going on over the sick-bed of Lady Curzon. In respect of medical skill, she has the best this country can offer. Watson Cheyne, who operated, is one of Lister's most distinguished pupils, and came with that great surgeon when he migrated from Edinburgh to London, nearly thirty years ago. He was for a long time Lister's assistant in his private practice, and it was owing to Lister's influence that he was appointed on the staff of King's College Hospital, where he now reigns in the place of his distinguished master. He is a typical Scot in appearance, a "son of the manse" with a truly Presbyterian austerity of manner and a full share of the "canniness" characteristic of his race. He has written much and well on septic diseases, and is a leading authority on cancer. He is a surgeon of sound judgment and a good, but not a brilliant, operator. Dr. Champneys is also a son of a clergyman, a Canon of the Church of England, and being an Oxford man, represents the culture which is here believed to be obtainable only at one of the older universities. He is on the staff of St. Bartholomew's Hospital, and is recognized as one of our foremost obstetricians; his professional character stands deservedly high. He was an ally of Sir John Williams, who has now retired from the smoke and bustle of active life, in his efforts to raise the standard of accuracy in gynecological statistics and generally improve the ethical tone of the profession. In this campaign both these champions of righteousness came into collision with Lawson Tait, at whom the "unco guid" always looked askance. Sir Thomas Barlow is an excellent all-round physician, who takes it somewhat ill that his name is still too much associated in the public mind with children's disease in which he first won

his reputation. He was physician to the household of Queen Victoria, and attended that sovereign in her last illness. In appearance, he is utterly unlike the typical fashionable physician, and he would not have described the death rattle in a queen's throat in the discreetly mysterious phrase used on that occasion by Sir R. Douglas Powell, who, in the bulletin announcing the passing away of the august patient said: "In the last few hours of life paresis of the pulmonary nerves set in, the heart beating steadily to the end."

The death of Finsen has been made the occasion of remarkable demonstrations of respect by crowned heads. Among them our own gracious sovereign has been conspicuous, having sent an autograph letter of condolence to the widow. Possibly this is to be explained as much by a wish on the part of His Majesty to please the Queen, as by any particular interest taken by King Edward in the discoverer of the light treatment. The Queen has been active in promoting the introduction of her fellow countryman's method in this country, and to her munificence is due the establishment of a light department at the London Hospital. Mr. Sydney Holland, the ruling spirit of that institution, was quick to perceive the splendid advertisement to be got out of the thing. He skilfully "nobbled" the Queen, went to Denmark in her train, and boomed the light treatment—and the London Hospital—in the press in a way which, were not charity supposed to cover the boldest advertising, might fairly be called indecent. And yet it is whispered by some who have seen the cases, that the results have been so unsatisfactory that the physicians did not care to publish them. However, this may be, no report, as far as I am aware, was published till this year when, at the annual meeting of the British Medical Association, Dr. J. H. Sequeria read a paper in which he stated that 216 cases treated by the Finsen light had been discharged as "cured." As no detailed report of the cases was vouchsafed, this bald statistical statement cannot be taken as proving much in favor of the treatment. Moreover, as the method has been in use only between two and three years at the London Hospital, any final conclusions on the subject must obviously be premature. Although Finsen himself, in his last publication, claims to have had only two per cent. of failures, it is well-known that several patients have been in attendance at the Copenhagen Light Institute ever since its establishment in 1896.

The *entente cordiale* between England and France is taking the form of fraternization among the members of the medical profession of the two countries. London is to be honored in October by a visit from a large party of French physicians, among whom are several men of note. These scientific pilgrims are to be taken to all the chief shrines of medical practice and research, and the arrangments for their hospitable entertainment are such as to dismay a person of average digestive power. It is characteristic of the pharisiasm of the profession in this country, that whereas at first the staffs of the great hospitals and the heads of laboratories were disposed to hold aloof, now when it has become clear that the thing is going to be a big success, they are scrambling to get into it. The promoters might well say, as Samuel Johnson did to Lord Chesterfield (I quote from memory): "Is not a patron, my Lord, one who watches, unconcerned, the struggles of a drowning man in the water, and when he has reached the shore, hastens to encumber him with help?"

Antivivisectors have a hospital of their own, about which the public has heard a good deal of late. The medical staff, as might be expected, is composed of men whose names are utterly unknown to the profession. One of these has now come forward—in the sensational papers—as the author of a "remarkable discovery" which is, if we are to believe his admirers, to revolutionize the treatment of defective vision. During the past twelve months, we are told, Mr. Stephen Smith, who is the author of a volume of antivivisectionist rant entitled *Scientific Research*, has excogitated what he calls a new plan of treating persons who hitherto have been obliged to wear spectacles. The other day "in the presence of a critical audience" he is said to have given a demonstration on patients whom he has treated. Cases of acute myopia, hypermetropia, and astigmatism were, we are asked to believe, shown to have been cured so far as to be able to dispense with spectacles. Some, it is alleged, are cured in a week, but in all cases the cure is rapid. According to a friendly scribe, "precisely what the method of treatment is remains the doctor's secret." It is stated, however, to consist in "manipulations of the eye"—an apt phrase which may be taken as describing the effect of the demonstration on the eyes of the "critical" spectators. An optician has challenged Mr. Smith to practice his method on half a dozen of test cases, of medium myopia, which he defines to mean cases which would need a correction of from —4.D. to —10.D. spectacles. He has further made the sporting offer that if these cases can be proved to the satisfaction of two British ophthalmic surgeons to be selected by himself and the *Daily Mail*, he will pay to a hospital the sum of $500. This challenge has been accepted by Mr. Smith, and we are therefore to have the curious spectacle of a therapeutic method in a highly technical province of the province of medicine tested "under the inspection" of the editor of the *Daily Mail!* In a statement made to a representative of another newspaper, of an even more "yellow" complexion, Mr. Smith is reported to have said that "the great bulk of cases are those of astigmatism, or errors of sight, and out of about thirty cases treated, I have found only three to be beyond improvement. Fifteen can see better than with their glasses, and are now cured, while in twelve cases the existing defects have been greatly mitigated." He added that this treatment consists in restoring the eyeball to its proper shape. "The eye defects coming under the headings of myopia (short sight), astigmatism (blurs and various errors of vision), and hypermetropia (long sight), are occasioned by various errors of shape in the eyeball. My method is to manipulate the eye, and thus correct errors of shape. This operation is painless and harmless." Mr. Smith's "discovery" would seem to threaten the extinction of the highly profitable industry of spectacle making, and even endanger the existence of specialists who profess to cure most of the ills that flesh is heir to with glasses. I do not think, however, that they need feel much alarm.

Mr. Colin Hunter, an associate of the Royal Academy and a distinguished artist, has just died under the hands of the Christian Science "healers." He had been suffering for nearly three years from cerebral softening and visceral complications. During all that time he has been under the care of Christian

Scientists. The one who was last in attendance, has stated that he was called in after six or seven "healers" had tried their powers on the patient, and the medical profession—apparently represented by homeopaths—had given the case up as hopeless. This particular "healer" claims to have cured Mr. Hunter of Bright's disease, liver disease, appendicitis, and other complaints including three paralytic strokes! Yet after all this tremendous expenditure of spiritual force the man died. Patients are so unreasonable. The case recalls that of our countryman, Harold Frederic, the well-known novelist, who died a few years ago in similar circumstances. Christian Science is said to be making headway in London, but about ninety-five of the adherents of Mother Eddy here are women and children, and the remainder are, what the poet calls, tenth transmitters of a foolish face, and sentimental persons in whom a vague mysticism has overclouded common sense. I believe the sect has not yet a church in London, although there are one or two meeting places where extracts from *Science and Health* are read to an audience, which to all appearance can lap itself in an elysium of mental vacuity akin to the Buddhist nirvana.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Surgery.

Stated Meeting, held October 7, 1904.

The President, Robert T. Morris, M.D., in the Chair.

Resection of the Greater Part of the Stomach and Transverse Colon for Carcinoma.—Dr. A. A. Berg presented a patient upon whom he had performed this operation. The man was sent to Mount Sinai Hospital with the diagnosis of malignant disease of the pyloric end of the stomach, which diagnosis was confirmed and the subsequent operation, although exceedingly difficult because of the extensive glandular involvement, had proved particularly successful in its results. All of the stomach except a small portion of the cardiac end had been removed and a gastrojejunostomy had been done using the Murphy button. During the course of the operation, the middle colic artery was ligated and divided after which the transverse colon became pale and anemic, and in consequence of this, for fear of the following, Dr. Berg considered it best to remove this portion of the gut, which he accordingly did, using here also the Murphy button. The whole operation had occupied two hours, and twenty-four hours after the operation, the patient was given food by mouth. Nine days later when the gauze drain, which had been left in leading out from the site of the duodenal wound, was removed, there was some leakage from the bowel but this had soon ceased and now, three months after the operation, the external wound was almost healed and having only a slight serous discharge. The patient is now eating full regular meals with comfort, and had gained eighteen pounds in weight. A test breakfast had been given him recently, and after the usual period only one ounce had been obtained. Dr. Berg said, that as the patient was now able to take a large quantity of food at a meal, it indicated that there must be a pouch formed for its retention.

The Value of Oxygen in Connection with All Anesthetisation. Dr James T. Gwathmey read this paper. He said, that his attention had first been drawn to this subject by the remarkable, and, to him unwarranted, difference that Hewitt, in his book on anesthetics had made between laughing gas and oxygen and laughing gas and air on the one hand, and chloroform and oxygen and chloroform and air on the other. According to Hewitt, it has never been established, beyond all doubt, that by employing a certain percentage of air with laughing gas, a better form of anesthesia can be obtained, and also that by using oxygen instead of atmospheric air a still better form of anesthesia is obtainable. In the same connection, he dismisses chloroform and oxygen by saying that he had had no experience with this combination. Dr. Gwathmey said that, theoretically, he believed oxygen to be indicated in every case where an anesthetic is used, and he had carried out a series of experiments on cats to demonstrate the application of this theory. Asphyxiation, he said, during the administration of an anesthetic, is produced by the diminution of oxygen and not by the increased amount of carbon dioxide. Pattan and Rumph had found a decrease of forty per cent. of carbon dioxide eliminated in the respiratory exchanges, and Richet had found a decrease of fifty per cent. in chloralized dogs. Berts' experiments with chloroform had shown a progressive diminution in oxygen absorbed and of carbon dioxide given off. Lorraine Smith had shown that dyspnea from change in gaseous composition of the blood may be due to a deficiency of oxygen while Richet had stated that blood which contains an anesthetic in solution, preserves, when shaken with air, its full ability for freeing oxygen. The object of giving oxygen instead of air with laughing gas, Dr. Gwathmey said, is to be able to replace the high percentage of useless nitrogen in the air by a corresponding amount of useful nitrogen oxide, the percentage of oxygen remaining the same. Cyanosis and other evidences of diminished blood oxygenization would thus be prevented. His experiments had been carried on with the Junker inhaler, which is the apparatus commonly used in England for the administration of anesthetics. In this method as now employed, there is no possibility of determining whether or not the patient is getting a sufficient amount of air at each inspiration. If the amount is insufficient, a terrific and needless strain is placed at once upon the heart, which, if repeated, could easily bring on a train of symptoms that it might be impossible to check. He had remedied this defect by placing an easily inflated rubber bag next to the inhaler and by keeping this two-thirds full, the danger had been eliminated. His experiments had proved that the combination of chloroform and oxygen practically eliminated danger from anesthesia and reduced the after effects almost to a minimum. He presented tables covering one hundred experiments to show the comparative time required to kill cats with chloroform and air, and with chloroform and oxygen. These showed that the time required in the first instance had been approximately one-half of that required in the latter case, which, Dr. Gwathmey said, suggested that chloroform and oxygen was twice as safe as chloroform and air, and was equally as safe as ether. He concluded his paper with the statement that oxygen increases the value of all anesthetics while it does not decrease the value of the anesthesia. Dr. Gwathmey then administered chloroform to two cats, giving air in combination with chloroform to one and

oxygen and chloroform to the other. The cat receiving chloroform and air died in twenty minutes, while the one receiving the oxygen was still breathing quietly at the end of fifty-one minutes when the experiment was abandoned. Another cat was given ether and air and it died in seventeen minutes. A marked difference was noted in the behavior of the cats receiving the air and those breathing oxygen with the anesthetic, in the later there being almost no muscular spasms and very little struggling and the breathing being more quiet. This, Dr. Gwathmey said, had been observed in all his former experiments.

Granulating Wound Adhesions,—A New Application in Preventive Treatment.—Dr. Frederic Griffith reviewed the histology of wound healing and said, that the healing of wounds is prevented by friction, and that this might be prevented by some substance having blood for a basis, thus doing away with powders, salves, oiled silk, etc., now in use. This, he said, would furnish a physiological non-irritating substance for coapted wound walls. He presented specimens of the peritoneum of the common gray or sand shark which, he said, if properly prepared, might furnish the desired protection. He further said, that there is a proprietary preparation on the market which is based somewhat upon the blood idea.

Dr. Griffith also presented several bone chisels which, he said, had been made to overcome the usual difficulty encountered, in that they were made much lighter in the handles than those commonly used.

NEW YORK ACADEMY OF MEDICINE.

Section on Obstetrics and Gynecology.

Stated Meeting, held October 6, 1904.

The President, A. Palmer Dudley, M.D., in the Chair.

The After-Effects of Hysterectomy on the Nervous System.—Dr. Graeme M. Hammond said, that much might be said in general concerning the effects of the removal of the uterus upon the nervous system and the manifestations of these in the subsequent life of the individual, but that he would confine his remarks to the effects upon the brain for this only was markedly influenced. The peripheral nervous system, he said, was not affected by hysterectomy to any appreciable extent. Paranoia, epilepsy, hystero-epilepsy or profound neurasthenia may follow the removal of the uterus and ovaries, but these were not the direct results of the removal. Psychoses were not produced by hysterectomy but were the result, if they followed the operation at all, of the shock due to the operation, just as these conditions might follow any major operation upon other organs or members. If delusional insanity, paranoia, epilepsy, hystero-epilepsy or neurasthenia follow hysterectomy, they would have occurred whether the operation had been performed or not. The tendency or condition productive of these nervous diseases was already present before the removal of the uterus, and this condition or tendency consisted of a defective nervous system, present since birth, or acquired at puberty, or was the result of long continued illness for the cure of which, probably, hysterectomy was considered. The surgeon should consider these pre-established conditions when considering the advisability of hysterectomy. He said in conclusion, that no disease is peculiar to women in whom hysterectomy had been performed, that the stopping of the menstrual flow had nothing to do with nervous diseases following hysterectomy, and that previous congenital conditions, defective brain or acquired neuroses at the time of operation independently causative of posthysterectomy diseased conditions of the nervous system.

On the General Health.—Dr. Eugene Coleman Savidge said, that just as in the removal of an arm or a leg after an injury, so in considering the advisability of a hysterectomy many cases are debatable when the choice lies between the removal of the uterus or death, the operation should always be performed, but that a portion of ovarian tissue should always be left. Ovarian substance is necessary to prevent the subsequent renal, cardiac and other disturbances, which so frequently follow the removal of all the ovarian tissue. In ten years' gynecological experience at Roosevelt Hospital he had found that in a large number of women, from whom the uterus had been removed, a condition of defeminization had resulted, as evidenced by the lusterless eye, the roughening of the skin and voice, increased hair growth, increased deposit of fat, and a wiping out of zest in life. The effect of the consciousness of barrenness was marked in almost every case. The more highly organized nervous systems of American women, as compared with European women, is to be considered always in the indications for or against hysterectomy, and this is particularly true of debatable cases and it should be remembered that in many conditions, treatment more conservative than hysterectomy may suffice.

On the Sexual Functions.—Dr. Hiram N. Vineberg said, that it is not possible to discuss this subject with authority, because American women will not talk of this subject. It usually had very little to do with the conditions for which women consult their physicians. Many women have no sexual passion whatever, many have a great deal and many who, because of undeveloped uteri, cannot conceive, have greatly exaggerated sexual desire. There are others, to whom the sexual act is extremely repulsive, who are very desirous of being fondled, embraced and kissed. Some writers, he said, believe that the pleasure derived from the sexual act is purely localized in the reproductive organs, and in substantiation of this they have cited cases in which the ovaries had been removed before puberty, and this had been followed by masculine appearance, hair on the face, no fat deposit in the mons veneris, etc. Other investigators believed that sexual desire is a mental process, but with this he did not agree. Among his own cases, and in the literature on the subject, he had found that hysterectomy had produced no diminishing effect on the sexual desire, while in some it had caused a marked increase, and in none of his own cases had he found that the sexual desire had diminished except where the change had been the result of the age of the patient. His conclusion was that whatever effect hysterectomy may have on the general condition of the patient, it has little or none on the sexual feeling.

Dr. Cragin, in the discussion said, that the after-effects of hysterectomy must be considered comparatively, considering the condition of the patient before the operation and the removal of the uterus only, or the uterus and ovaries produce different effects. He did not agree with Dr. Hammond in

regard to his ideas of the effect upon the nervous system, and said, that his experience had taught him that a more profound effect was produced upon the nervous system by hysterectomy than by operations upon other organs. He said, that the cases which Dr. Savidge had observed in Roosevelt Hospital, were those cases which had been operated upon when the value of leaving ovarian tissue was not so well known, and when in consequence, the uterus and ovaries had been removed entirely. This, he said, produced more profound shock to the patient, and the after-effects were more marked, than when some ovarian substance had been left. When the ovaries or a part of them are left, removal of the uterus has comparatively little effect, and that certainly when hysterectomy is done for diseased conditions, the remaining condition is vastly better than before the operation. He further said, that if the cervix is left, at the time of removal of the uterus, and especially if part of the ovaries is left, the effect upon the marital relations is very small indeed. If, however, the cervix and ovaries be removed with the uterus, a marked decrease in the size of the vagina often followed, preventing the sexual act. In considering hysterectomy for diseased conditions, he said, that the danger to the life of the patient should be considered on the one hand, while on the other were comparatively minor effects of a vasomotor character.

Dr. Goffe said, that removal of the uterus removes the child-bearing function only, and that it has no effect upon sexual enjoyment, but that the loss of possible motherhood was well worth considering. The general mental, moral and emotional condition of the woman who has borne children should be weighed in comparison with that of the one who has not. He quoted Dr. Beebe, of Cincinnati, as believing that the ovary has to do with development and that sexual desire is located in the brain, but he said, that he himself considered that the ovary is the determining factor of sexual desire. He said, that many observers who had questioned patients whose uteri had been removed, report no effects upon sexual desire, but that the general health of the patient is the true test of her condition after hysterectomy, and they have stood the test in the majority of his patients notwithstanding the numerous nervous explosions which have sometimes occurred.

Dr. W. G. Wylie said, that he removed the ovaries only for diseased conditions, never for nervous troubles, and that he did not agree with Dr. Hammond, as he believed that the removal of the uterus sometimes produced nervous conditions or even melancholia. He said that this was particularly true in women under thirty years of age. Removal of the uterus from young women frequently produced vaginismus to a very marked degree. He also said, that all of the Fallopian tubes should be removed with the uterus.

Dr. Hammond said, in closing, that the integrity of the nervous system does not depend upon the ovaries. He had seen many cases to prove this, and that he had also seen a simple curettage followed by profound neurasthenia while he had seen many, upon whom hysterectomy had been performed, possessing perfect health.

Dr. Savidge further said, that the sexual passion many times persists after the menopause which would argue against the idea of hysterectomy diminishing sexual desire.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Fifty-fourth Annual Meeting, held at Pittsburg, September 27, 28 and 29, 1904.

SECOND DAY—SEPTEMBER 28.—*Continued.*

(Continued from Page 720.)

The Removal of Internal Hemorrhoids by Excision.—Dr. Ernest Laplace, of Philadelphia, described the operation as follows: The patient is prepared as usual; placed on the left side, with the thighs flexed upon the abdomen. The sphincter ani is paralyzed by stretching with the thumbs. The hemorrhoidal area is brought into view by clamping with forceps each hemorrhoid at its upper and lower extremity, parallel with the length of the rectum. A curved Hagedorn needle, armed with No. 2 plain cumolized catgut is now passed immediately above the upper forceps, through the healthy mucous membrane, and the catgut suture is tied. The upper forceps being held in the left hand and drawn, the hemorrhoid will now be cut with curved scissors just enough to allow the cut to be closed by the immediate insertion of a continous suture with the needle just used. This first cut being closed, the hemorrhoid is again cut a little, and the wound closed by the same continuous stitch, and so the procedure is repeated until the hemorrhoid is removed, when the suture is finally tied. Should any hemorrhage occur another whipped suture is applied locally and controls it. Each hemorrhoid is dealt with in this way, until sufficient of the hemorrhoidal area is removed. Eighty-three cases have been operated upon by this method in the last four years, with most satisfactory results. Patients have been sent home as early as the second day after operation, there being no danger from hemorrhage, or sepsis, and the catgut taking care of itself and dropping out spontaneously. Delicate longitudinal scars are formed corresponding with each hemorrhoid that has been removed. The advantages claimed for the method, are precision, absence of hemorrhage, during or after the operation, safety and simplicity, as well as a minimum of pain.

Retrodisplacement of the Uterus.—Dr. Henry D. Beyea, of Philadelphia, divided the case into (1) acute retrodisplacement and (2) chronic retrodisplacement, in the former of which when uncomplicated he had found the most satisfactory treatment to be the application of a properly fitted Smith or Hodge pessary. He gave in detail the technic of the operation, and in his 465 patients, one only had died; there had been no complications attending subsequent gestations or labors, and 95 per cent. of those from whom he had been able to receive reports, have had complete relief of symptoms or improvement in health.

Dr. Charles P. Noble, of Philadelphia, in discussing this paper, stated that the only class of cases in which he had found the pessary of value was in those following labor, in which with rest treatment, about one-third had been cured. In the surgical treatment he divided the cases into the classes in which the appendages were diseased, and those in which they were normal, in the latter of which he preferred the Alexander operation. He also was favorably inclined toward the operation described by the author, but felt that the percentage of failures was somewhat larger than with the Alexander operation.

Disturbance of Menstruation and Their Significance.—Dr. E. E. Montgomery, of Philadelphia, went carefully into the causes of the flow, and considered the disturbed conditions under amenorrhea, which may be either congenital constitutional or mechanical; dysmenorrhea, which owing to the present mode of dress is rapidly increasing; menorrhagia and metrorrhagia, and viacrious menstruation, a discharge periodically from some other surface than the uterine mucosa.

Overlapping of the Aponeurosis in the Closure of Abdominal Wounds.—Dr. Charles P. Noble, of Philadelphia, said that he had first used this procedure in 1894 for umbilical hernia, and since 1897 had employed it in all incisions in over 150 cases, as by overlapping the aponeurosis in this way you can secure firmer union than by any other method.

Pernicious Vomiting of Seven Years' Duration Cured by Suspension of the Kidney.—Dr. George Erety Shoemaker, of Philadelphia, reported the case of a woman aged twenty-eight years, who had an attack of typhoid fever seven years before, accompanied by hemorrhage from the bowel and vomiting of blood, and followed by phlebitis of both lower extremities, and nausea and vomiting occurring three or four times a day and induced during the latter time, not only by taking food but by nervous excitement. These were worse near the menstrual period. During this seven years she had subsisted mainly upon infants foods, and had undergone various treatments, including rest, lavage and dilation of the uterus, the latter being followed by some temporary benefit. Upon admission to the hospital, the right kidney was found to have descended to the level of the umbilicus, replacement of which and the removal of the left tube, ovary and appendix was followed by complete recovery.

Tumors of the Cerebellum and Cerebellopontile Angle.—Drs. Charles K. Mills and Charles H. Frazier, of Philadelphia, stated that the existence in the cerebellum or its immediate environs of a tumor was comparatively easy of diagnosis, the symptoms being optic neuritis, headache, vertigo, nausea and vomiting, asthenia, atonia and nystagmus, but the localization thereof is not an easy task. The author stated that the eighth nerve was the most common seat of tumors of the cerebellopontile angle, the symptoms being impairment or loss of hearing with tinnitus, often associated with facial, trigeminal and ocular paresis on the side of the lesion, ataxia and the general symptoms of brain tumor. In conclusion, Dr. Mills insisted upon early operation, in the first place, to remove the tumor when this was possible, and secondly, when successful removal cannot be hoped for, to relieve the urgent and distressing and destroying general symptoms, such as headache and optic neuritis.

Section A.—*Continued.*

Tympanites.—Dr. J. C. O'Day, of Oil City, referred to an unfortunate experience in his first case of obstinate tympanites not operated upon. While believing with Miles F. Porter that needle puncture is unsurgical, he is convinced from an experience of two cases that the operation should be encouraged, inasmuch as its dangers are nil, and because many, untrained in the use of the knife, could resort to this simple procedure with successful result. Two cases were cited which had been treated by needle puncture with perfect recovery.

Glimpses of Auto-Intoxication.—Dr. Edwin W. Moore, of Franklin, held that the real cause of auto-intoxication is an unsolved mystery, and claimed that perverted nutrition and cell destruction affords sufficient cause to justify it a place as a causative factor in disease. He mentioned the various actions of the liver, and suggested a difference in the area of its production and that resulting from the metabolism of tissue. He separated auto-intoxication from infection by giving to the infection theorists all conditions of exogenous origin and to the auto-intoxication investigators those of endogenous origin. He admits a large field of toxemias between these extremes as unclassified and of no known definite origin. He specializes rheumatism, gout, many nervous diseases, jaundice from obstruction, Addison's disease and many gastro-enteric conditions as auto-intoxications, and questions the right of investigators in claiming anemia as an infection.

Symptomatology and Treatment of Influenza.—Dr. Samuel Wolfe, of Philadelphia, said that the history of influenza, recurring since 1889, showed characteristic deviations from the classical type, but that the affinity of the specific cause for mucous membranes and nervous structures is constantly demonstrated. There is reason to believe that certain symptoms are caused by the bacillus itself, and certain others by the toxin resulting from it, but strict differentiation is not yet practicable. The treatment aims at the control and mitigation of such conditions as fever, pain, catarrhal inflammations and central nervous derangements. Facilitating the elimination of the toxin must be regarded as important.

Pleurisy with Effusion.—Dr. J. E. Rigg, of Wilkinsburg, in this paper considered the influence of the teaching of pathological anatomy and bacteriology as causative factors and for classification, and the value of impartial clinical observations; also the frequency of pleurisy as found at autopsies, the forms of pleurisy, tuberculosis as a predisposing cause, and cold, traumatism and infection as exciting causes. The relative frequency of pleurisy with effusion to empyema was referred to. Under symptoms and diagnosis the author treated of friction, pain direct and reflected; the presence of respiratory sound and the use of the aspirator as a means of diagnosis and why it at times fails. In treatment the value of blisters in the early stage was discussed, the optional use of the aspirator, with the positive signs for the prompt use of the aspirator. The value of tincture of aconite combined with belladonna is mentioned

Pneumonia.—Dr. John R. McCartey, of Fredonia, is at variance with those advocating the expectant treatment. He brings forward spirit of chloroform, which, from thirty-two years' experience with it, he considers specific when given early. The author cited two cases. The first, seen as soon as the patient emerged from severe chill, was given 20 minims every 15 minutes for six doses and every hour thereafter; dismissed the next day. In the second case the patient was seen eight hours after initial chill and dismissed on the third day. The remedy is of no avail after hepatization is established. He usually combines aconite with it now. Salicylic acid alone will cure and abort pneumonia by its antiseptic action. Dr. McCartey gives it by absorption by dissolving it in gasoline and applying it externally. Ergot was mentioned as of much value. His mortality has been but 2 per cent.

Blood Analysis.—Dr. J. M. McNall, of Wilkinsburg, referred to the advantages of blood analysis.

The definition of leucocytosis was given with its varieties, absolute and relative, and emphasis given to the importance of relative count and leucocyte curve. Blood analysis, it was stated, was probably no more applicable than in the leucemias and anemias. Pernicious anemia was considered and its relation to secondary; its faulty hematogenesis and hematolysis, characteristic marrow lesion and cells, their embryonic type. Other generative changes and findings were given. The blood picture of anemia was given with its differentiation from pernicious anemia. The limitations and requirements of blood analysis were outlined.

Sea-Bathing.—Dr. Philip Marvel, of Atlantic City, N. J., referred to the great antiquity of sea-bathing as a curative for bodily ills. The influence of temperature, physical conditions of the atmosphere, the physical and mental condition of the individual and the fact that the water is truly a mineral water, were facts not to be lost sight of. Observations were noted of the slowing or enfeeblement of the pulse of those submerged for hours in the sea and of those immersed for a time in water at a temperature higher than that of the body with a lowering in the systemic resistance. He believes that sea-bathing, as practised on the Atlantic coast, is responsible for greater harm than good, and he believes that physicians have been too long silent on the subject. They should impress upon those under their care the advantages of a short exposure, not exceeding thirty minutes, and the necessity for prompt and positive reaction. Sea-bathing is indicated in those weakened conditions where normal metabolism is inhibited or perverted nutrition exists, and is contraindicated where the arterial elasticity has been changed or lost, as in arteriosclerosis and capillary fibrosis; also in those cases in which the peripheral vessels have ceased to respond to reflex stimuli, in any condition in which the stimulation would favor internal hemorrhage; in case of chronic heart disease and in cases in which lowered resistance necessitates more than ordinary care of the patient's forces.

Some Remarks on Physical Diagnosis: (a) Ulnar Palpation; (b) Transmanual Auscultation.—Dr. David Reisman, of Philadelphia, designated as (*a*) ulnar palpation a method of palpation which he believes gives more satisfactory results that the one commonly employed, namely: The laying on of the flat of the hand while the patient is speaking. Dr. Reisman's method consists in applying the ulnar surface of the hand and little finger into each interspace, the hand being held perpendicularly to the chest. The method enables one to discover small shades of difference in the fremitus of contiguous interspaces or corresponding areas of the two sides. It also shows accurately the upper level of an effusion and the limits of a plastic exudate. It is of most value in examining the front of the chest, but may be also used for the back. (*b*) After speaking of the difficulties of the method of timing heart murmurs and of the unsatisfactory results generally given by timing murmurs by means of the carotid pulse, Dr. Riesman described a method which overcame some of the difficulties. It consists in auscultating with the binaural stethoscope through the hand placed over the apex beat. By this method the apex beat is felt and the murmur heard at the same point and timing becomes easy. The best stethoscope for the purpose is one provided with a diaphragm. Not only is it possible to hear murmurs plainly through the hand, but almost as satisfactory results can be obtained by placing a finger flexed at a right angle on the apex and then resting the stethoscope on the finger. The principal advantage of transmanual auscultation is found in the differentiation of presystolic from systolic murmurs. It is also of use in timing musical and other peculiar murmurs heard over the chest. The successful application of the method presupposes the existence of a palpable heart. Both methods were illustrated with photographs.

Myocardial Degeneration.—Dr. Albert E. Roussel, of Philadelphia, stated that if the statistics of Schott were accepted, it would be found that diseases of the myocardium were more frequent than those of the endocardium in the proportion of 505 to 245. He believed that arteriosclerosis must be accepted as an important factor in many cases of cardiac degeneration. He considered it worthy of remembrance that at least partial occlusion of the coronary arteries due to this cause may be compensated through the vessels of Thebesius with avoidance of the otherwise resulting damage. Parenchymatous degeneration, fatty heart and allied conditions were considered with their etiology and treatment. The diagnosis of many cases of fatty degeneration the author believes, more difficult than that of a fibroid heart, and he is confident that often cases of this disease are not recognized even after a physical examination. This is because the size of the heart in simple fatty degeneration is little changed, and the area of dulness presents no alteration.

Practical Points Concerning Smallpox.—Dr. William M. Davis, of Pittsburg, in this paper emphasized the importance of taking into consideration the entire symptom complex. Contrary to some opinions, he believes the primary fever to be quite contagious. The varieties of smallpox in reference to diagnosis and prognosis were discussed. The treatment of corneal ulceration, a frequent complication, was detailed.

THIRD DAY—SEPTEMBER 29.

Section A.

Test for Blood in the Feces and Its Clinical Significance.—Dr. J. Dutton Steele, of Philadelphia, said that by occult is meant an amount of blood so small that it cannot be recognized by the naked eye or by the microscope. It has been found by certain German observers that the old guaiac test for hemoglobin can be so modified as to detect extremely small amounts of blood in the feces. They have applied this test in the diagnosis of all lesions of the gastro-intestinal tract that cause hemorrhage. It is of special value in the diagnosis of gastric carcinoma and gastric and duodenal ulcers. The blood is constantly present in the stools of carcinoma, and is intermittently present in cases of gastric and duodenal ulcer and organic but benign stricture of the pyloris. Dr. Steele reported seven cases in which the test had been applied and in which the test appeared to be as valuable as is claimed for it. He is of the opinion that the method is a distinct advance in the diagnosis of gastro-intestinal diseases, and will soon rank with such symptoms as the absence of hydrochloric acid in cancer or hyperacidity in ulcer.

Tuberculosis of the Gastro-Intestinal Tract.—Dr. J. A. Lichty, of Pittsburg, presented this contribution. The patient, thirty-six years of age, had no pulmonary signs, but had alternate diarrhea and

constipation. She had been exposed to tuberculosis for five years. At autopsy a perforation of the bowels was found near the ileocecal valve. Partial obstruction was present at the splenic flexure of the colon. The modes of infection of the gastro-intestinal tract were given as *primary;* (*a*) by inspiration, (*b*) by kissing, (*c*) by dirty objects or contaminated hands which find access to the mouth, (*d*) food from infected animals, or food which accidentally becomes infected; *or secondary,* that is, from the swallowing of sputum which is tuberculous.

The Diagnosis of Cirrhosis of the Liver.—Dr. Alfred Stengel, of Philadelphia, stated that cirrhosis of the liver is usually recognized when the disease has reached a practically incurable stage. This statement, however, Dr. Stengel said, needs some modification, for occasionally, cases not recognized until ascites and other signs of portal obstruction have developed recover from these striking symptoms and survive, which is probably due to the fact that with the terminal cirrhotic change in the liver there is always a considerable amount of cellular infiltration which is removable. The speaker referred to a certain train of symptoms met with in the earlier stages of cases of cirrhosis as well as in other conditions, and then proceeded to a discussion of the differential diagnosis. With regard to the occurrence of enlargement in the early stage of cirrhosis, the speaker stated that, contrary to the opinion of Leube, he had watched cases of cirrhosis from a stage when the liver was enlarged to the terminal contracted condition. The symptoms in congestion are practically those that usually are seen, but there is always found some adequate circulatory cause for the congestion, some form of cardiac or obstructive pulmonary disease which prevents the proper circulation of the blood, the most frequent cause being cardiac or circulatory weakness, the congestion is found to fluctuate with the fluctuations in the underlying condition. Dr. Stengel referred to the chemistry of cirrhosis and stated, that the only test that had proved of any value, and this merely confirmative, is that for urobilin. Among the conditions causing the train of symptoms met with, cirrhosis is the only one which regularly produces urobilinuria. Finally, in referring to the physical examination for cirrhosis in its more advanced stages, the speaker warned against a too ready acceptance of the results of percussion as an indication of decrease in the size of the spleen, and advocated a more general appreciation of the value of splenic enlargement in the diagnosis of cirrhosis of the liver.

Dr. David L. Edsall, of Philadelphia, referred to alimentary levulosuria as one of the chemical methods used in the diagnosis of liver disease. Strauss administered 100 grams of levulose on an empty stomach, and determined that levulose appeared in the urine in a large proportion of cases of liver disease, but in only a small proportion of cases of disease of other kinds. Dr. Edsall, from his own results and those of others, is skeptical as to the diagnostic value of this test. He emphasized the ease with which the test for urobilinuria may be carried out when the method of Hammerschlag is used. A test which Dr. Edsall has used and which he still looks upon with an entirely tentative judgment, but which has seemed to him to be quite as valuable as urobilinuria, is the determination of large amounts of phenol in the urine. He first used this test for the reason that the liver has the function of destroying the products of putrefaction that come from the gastro-intestinal tract or otherwise protecting the organism from them.. He thought that it would be worth while to determine to what extent these products of putrefaction escape into the general circulation and then into the urine in liver disease, as a loss of the liver's function, more or less complete might be indicated by their escape in abnormal quantity. Of the various substances that Dr. Edsall investigated in this connection, he found that phenol alone seemed to show reasonably characteristic changes. While this substance is variable in liver disease, it does seem to him that a very large amount of phenol in the urine is strongly suggestive of liver disease when other evident reasons for its presence are absent.

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

SECTION ON PATHOLOGY.—*Continued.*

(Continued from Page 672.)

Some New Lines of Inquiry.—He next referred to three pieces of work which he thought opens up vistas of much significance. The first of these is the work of Meyer and Ransome. In this research these observers, extending the observations of others, have established the fact that tetanus toxin reaches the nerve cells by means of the motor axones only. They have also brought out certain very striking facts regarding the action of antitoxin. It has been usual to suppose that if a sufficient amount of antitoxin were injected, toxin might subsequently be injected freely without any disease resulting. But the observers referred to have shown that even the injection of a very large excess of antitoxin is insufficient to entirely protect an animal if the subsequent injection even of a small amount of toxin be practised in a motor nerve. From this they argue that while the toxin reaches the nerve cells by the protoplasm of the axones, antitoxin only reaches them by the very much more round-about route of the lymphatics. But much more important is their observation that even in an animal actively immunized against tetanus, and possessing a fairly potent antitoxic serum, this fact will not prevent the development of tetanus if the toxin be injected into a motor nerve. If this observation is confirmed, then it appears unlikely that, as Ehrlich had held, antitoxin is formed in the nerve cells. In this respect Ehrlich's theory was largely founded on the observations of Wassermann and Takaki on the fixation of tetanus toxin in the brain of susceptible animals. Though the validity of this observation has not been denied, yet the interpretation has given rise to much dispute, and we must admit that at present we know of no definite facts which point to the place of origin of antitoxin. If antitoxin be not formed in the susceptible cells, one difficulty which existed in accepting Ehrlich's original view is removed—namely, what becomes of the toxophorous affinities during the process of immunization when the cell is being bombarded with fresh amounts of toxin. The view that the saturation of the side chains of the cell with toxin made them drop off with their burden of toxin always appeared to him to be hardly tenable, in view of the fact originally put forward by Ehrlich that the reason for the affinity of toxin for the cell was probably to be found in the fact that the toxin closely resem-

bled the normal food of the cell. It would be of little use to the cell if a side chain should straightway drop off into the serum whenever a food particle became attached to it. The whole view was too theoretical. The second piece of modern work calling for attention as a new departure is that of Muir, which appears to him to be the most important of all the recent contributions to the interactions of the constituents of hemolytic serums. Muir has investigated further the observations of Ehrlich that in blood corpuscles probably there exist more affinities capable of being saturated by immune body than those which are actually concerned in hemolysis when complement is supplied. He has shown that when corpuscles are thoroughly saturated with immune body, it is possible to dissociate a certain amount of the immune body and to cause it to become attached to fresh corpuscles. A not unimportant aspect of this observation is the deduction following from it that an exchange of molecules can take place between cells when these cells are merely in contact with each other. Further, Muir shows that for each moiety of immune body taken up by corpuscles a corresponding amount of complement can be taken up. This establishment of a definite quantitative relationship in the reaction suggests a definite chemical reaction between immune body, complement, and red blood corpuscles, and is opposed to the view of Bordet and the French school generally that the action of immune body is what they describe as a sensitization. But Muir's most important observation here is that after red blood corpuscles have taken up as much immune body as they are capable of, and when to the combination as much complement has been added as again can be taken up, still some of the immune body but none of the complement can be dissociated from the combination, and this immune body is dissociated in the original form in which it became attached, that is, it does not bring off any complement in combination with it. As Muir points out—and the observation is of very great weight—such an experiment seems incompatible with Ehrlich's view that immune body forms a link between the red blood cells and complement. In his latest work (with Browning) Muir brings forward evidence that the lysis by complement of red blood corpuscles saturated with immune body alters the affinity of these corpuscles for the weakened complementary bodies or complementoids which can be produced from complements by heat. This observation, taken along with the earlier results, opens up entirely new questions regarding the relationship of immune body which in the near future will demand an answer. The third work to which he referred is that of Wright and Douglas. As is well known, the question of the exact part played by the act of the ingestion of bacteria by cells in the killing of these bacteria, has for long been in a most unsatisfactory position. Phagocytosis is an indisputable fact which every bacteriologist has constantly before him under the microscope, but under what circumstances it occurs, and by what laws it is governed, constitute questions to which no answer could be given. But one cannot help feeling that the investigators named have by their work given ground for the hope that before long some of the much-needed light will be forthcoming. For one thing, Wright, by the elaboration of methods of the highest precision, had previously laid the foundation for the attack on the problems on which he is now engaged. And further, thanks to the beautiful method of Leishman, we have now a means of measuring exactly the phagocytic power of a cell by counting how many bacteria it can ingest in a given time. These observers have made a weighty contribution to our knowledge of the relative parts played by the bactericidal power of the serum, and by the intracellular destruction of bacteria. They have shown that in the case of the normal man some bacteria are killed extracellularly, whilst with others the serum has no bactericidal effect, but phagocytosis is the prominent feature when these bacteria are introduced into the blood. Wright and Douglas have further shown that, when bacteria are ingested, in the case examined these bacteria are previously sensitized by union with a substance existing in the plasma, and which Wright and Douglas call an opsonin. What these opsonins are, and whence they come, is a matter for the future, but any one who has had to plod wearily across the acres of barren papers which have hitherto formed the literature of phagocytosis will feel that the edge of the desert has been at length reached.

While the precise inter-relations of the substances concerned in the actual killing of bacteria, and, it may be, the possible variations in the processes at work in individual cases must occupy much attention in the near future, the work of Wright and Douglas raises another question, namely, of how far the struggle between bacteria on the one hand and the bodily cells on the other does not involve in the case of the latter a symbiosis between different types of cells or between different activities of the same cells. The attempt to answer this question, taken along with all the existing evidence for the idea that cells work through the agency of chemical substances will inevitably lead to a closer inquiry than has hitherto taken place into the sources of the, it may be, varied substances which require to come into activity in any one case. And it is here that our discussion to-day touches very closely that of to-morrow on the rôle of the lymphocyte. The outstanding feature in an infection is the state of embryonic activity into which the wandering cells and endothelia of the body are thrown. Part of this activity may be toxic in origin, and may be looked on as the result of an injury to cells, part may be of the nature of a response to what may be called physiological injury, that is, an injury which results in more work being done. We are ignorant of the true nature of the principles underlying this process connected, as it must be, with hypertrophy as a whole. At present we can only admit as a fact that when a tissue requires to do more work more work is done. In the present case the greater work done by the increased number of cells may be partly of a mere scavenging character. The result may only be that the toxic remains of bacteria may be swept out of existence. But part of the work may be the elaboration of the chemical substances required for the active killing of bacteria or for the building up of antitoxic material. Prima facie there is a case for the wandering cells of the body and especially the leucocytes playing a part in these processes. What exactly that part may be and whether other cells in the bodily organs also take most striking at present is that with all the work which is being done in hematology, we still require more light on the nature and functions of such cells and, especially in relation to immunity, we need parallel observations in which the chemical proper-

ties of the blood are correlated with its microscopic character. Much help might also come from further study of the comparative morphology of the leucocytes, and here the work of Gulland, and lately of such workers as Hirschfield and Meinertz, has opened up the way for further advance. In this connection the most striking feature seems to be the fact that in nearly all mammalia, and even in many fishes and birds, the cells most uniformly found are of the type of which the large hyaline cell and the small cell with basophilic granules in its protoplasm, occurring in man, are the most familiar examples. But the most interesting fact that comes out from this study is the extraordinary diversity which occurs in the animal series in the cells of which the polymorphonucleate cell is the type. With regard to them, we are still far from appreciating what the significance of minute differences in form and granulation signify. Some light might come on this problem by the comparative inquiry involved in the study of the same infection in animals with corpuscles of different forms. Whatever line of research here is fruitful, it is certain that the study of immunity will not be complete till we know not only the substances concerned in the processes of high immunization and of ordinary resistance to a first attack of disease and the interrelation of these substances, but also the sources from which these substances are derived and the laws which govern their formation. From our present standpoint, no knowledge would be in this connection more interesting or important than the knowledge of the precise part played by wandering cells in the nutrition of the lower forms of life. As Ehrlich pointed out, both toxins and the constituents of the bacterial protoplasm must in chemical composition closely resemble the ordinary food material of animal cells. The further fact of the existence in the blood serum of substances closely allied to immune bodies points to a close relationship between the principles underlying immunity and some process of ordinary metabolism. The only other view which might be put forward is that the qualities to which immunity is due have come from the survival of the most immune. Such a hypothesis is difficult to maintain in view of the ease with which new and artificial disease conditions can be brought into existence at the will of the pathologist and of the conditions of natural immunity which are found to obtain against these artificial diseases. All the facts indicate that when the subject of immunity begins to be more clearly opened out it may be found that the methods by which the effects of an invading bacterium are met are merely special manifestations of the normal interdependence of groups of the bodily cells one on another.

Historical Résumé.—In continuing the discussion William Bulloch, of London, gave an excellent historical and critical summary of the various sides of the general subject without indicating more than the drift of the present series of inquiry.

Agglutinins.—Georges Dreyer, of Copenhagen, spoke of some results obtained in the study of the agglutinating substances of the colon bacillus. Agglutination by heat, by acids, and by alkalies, were discussed.

Section on Tropical Medicine.

Prophylaxis of Malaria.—An important discussion of this topic was taken up by Drs. Jos. Stephens, Rose, Duncan, James, Christopher and others: Dr. Stephens said, that it may help to make more precise his views if, instead of recounting the methods of prophylaxis used and the results achieved in Italy, in British, French, and German tropical possessions, in Japan, he considered some scientific aspects of the problem which in many of the publications on this subject seem to have been overlooked. It is, he thought, not unnecessary to point out even now how malaria is contracted. It has been for centuries believed that malaria is contracted from the vapor of marshes; and now that certain mosquitoes are proved to be the cause, it is not uncommon to overlook the means whereby the mosquito produces malaria, and still to attribute malaria to the presence of the water in which the mosquito breeds, the "shallow pools," etc. It seems that this is to take a wrong standpoint, that the public should be educated to regard not the pool, not the mosquito, not even the anopheline, as the source of danger, but the infected anopheline; and he would go further: he would have everybody clearly understand how it is that the anopheline becomes infected—that is, can convey malaria. It results from the fact which, he believes, not 1 in 100 laymen in the tropics knows—that malaria is a contagious disease. The source of contagion unsuspected by the laymen lies in the fact that in the tropics the native population, especially the child population, carries malaria parasites in its blood; that it does so, often while presenting not the least outward sign of sickness. It is this apparently healthy but actually highly infected population which is the great source of malaria parasites, and hence of danger, to the European. It is from the native that the malaria-bearing mosquito gets its parasites, and these it transmits again after the lapse. The native population may show no outward sign of sickness. The native also dies from malaria, but if one wishes to see malaria in its severest forms, let him visit some up-country miner's camp or Europeon settlement in the bush. There he will find those "malarial wrecks," the fever-stricken pioneers, "down with fever," as it is called, vomiting incessantly, with a temperature of 105° F., in constant dread of black-water fever, which not uncommonly supervenes. Those who live in the towns not uncommonly forget that it is in these out-stations that malaria exists in its most virulent form. He dwelt on this condition, because it is the lot of these unfortunate Europeans to fill the "white man's grave," because he thought that in schemes for eradicating malaria they are forgotten.

Contagiousness of Malaria.—Malaria is a contagious disease. It has been the great discovery of Ross, that it is a certain mosquito that conveys the contagion. We know that certain mosquitoes, of the subfamily *Anophelina*, alone can convey the contagion. Of anophelines there exists about a hundred species. Which of these, or do all of them in different parts of the world convey malaria? It is surprising that on this point there is but scanty information.

The number of species that are known to convey malaria may almost be counted on ten fingers. They are in Europe—*A. maculipennis* (mainly); *A. bifurcatus* (less concerned); *P. superpictus; M. pseudopictus* (especially in some parts). In Africa *A. maculipennis* (in Algeria); *P. costalis* and *M. funesta* (especially in tropical Africa), and *P. Chaudoyei*. In India *M. listoni. M. culicifacies, N. maculipalpis* (?). In North America *A. maculipennis*. In West Indies *Cc. albipes*, that is, a dozen species only of which we can say with any certainty they convey malaria, out of nearly a hundred existing species. But it may be urged if one species conveys malaria another will; that is not a scientific argument, and nothing short of actual proof

should be allowed to satisfy us. One can go further, and say that the profession has a certain amount of evidence, gradually increasing, to show that all species do not convey malaria. He recalled the results obtained by Christophers and himself in India. They formed the hypothesis, based upon general observations, that all species of anophelines were not concerned in the transmission of malaria. They put this hypothesis to the test in two very malarial places in India—Mian Mir (Punjab) and Ennur (Madras). They caught in the same huts, at the same time, in these two far distant places two species of anophelines—*M. rossii* and *M. culicifacies*. They determined by actual dissection which of these species contained parasites (sporozoits), and found as follows:

In Mian Mir.

—	Number Dissected.	Number Infected.	Percentage.
M. culicifacies . .	259	12	4.6
M. rossii	496	0	0
In Ennur.			
M. culicifacies . .	69	6	8.6
M. rossii	364	0	0

So that *M. rossii* was not carrying malaria under conditions where *M. culicifacies* was. These observations have been repeated by others and the result is always the same. *M. rossii* does not in nature convey malaria. This, while scientifically of great interest, is also of practical value. Shall money and time be spent in eradicating *M. rossii* when as far as one knows it is not concerned in the transmission of malaria? These mosquitoes exist in myriads in Calcutta, Madras, Bombay, and in large towns, and are believed to be harmless.

Whether *A. punctipennis* conveys malaria in nature remains to be seen. Similar results (unpublished) have been obtained in Japan. These results, then, show that certain species of anophelines do not convey malaria, and on general grounds there is little evidence to connect those species which we know as "wild" mosquitoes with the transmission of malaria. Anyhow, it should not suffice to state simply "the *Anopheles* was found" without stating what species of anopheline; but, most important of all, it should be determined by actual dissection whether or no that species does transmit malaria. The practical bearing of these facts is obvious. If we can positively state that a certain species of anopheline does not transmit malaria, it will obviously simplify operations directed against mosquitoes. Another point of great interest in connection with anophelines is their breeding grounds. Take again the two Indian species mentioned above, *M. rossii* and *M. culicifacies*. Christophers and Stephens showed in India that, broadly speaking, each anopheline has a breeding ground of its own. At any rate, in the case of the above two species they are totally distinct and different in nature, and whereas *M. rossii* breeds in the shallow pool or puddle some inches deep only, *M. culicifacies* does nothing of the kind. It is never found breeding in these dirty puddles; it loves clear, fresh water, of streams, rivers, canals, and other moving water, where it occurs in myriads. Now if these results are true, that *M. rossii* does not carry malaria, and no doubt has yet been thrown on them, it means that it is unnecessary to attack the breeding grounds of *M. rossii*. This means an immense saving in labor and expense, for even during the dry season the pools in which *M. rossii* breeds are very numerous, and during the rains they are legion. Minute work, then, is still required on breeding grounds on the habits of larvæ, their enemies, fish, beetle, beetle larvæ, and the like, natural larvicides so to speak, all these points may be of great practical import.

The Flight of Mosquitoes.—Then, again, there is a question of flight of mosquitoes, a very important problem. Christophers and Stephens were constantly engaged in trying to make observations on this point, because we used to read alarming statements published by hasty writers that mosquitoes (genus and species it is needless to say not mentioned) flew fifteen miles, so that it seemed to us, if it were so, whatever might be done to free a place from anophelines there was nothing to prevent some of these long fliers coming, with parasites in them, into a district just made free and undoing all one's labors. But close observations convinced them that nothing of the kind happened, or perhaps, to be strictly accurate, did not happen under the conditions they knew of, and all their observations repeatedly made and checked, tended to show that the normal flight of anophelines was a matter of some hundred yards and not miles. Thus they observed that the center of Freetown, the capital of Sierra Leone, was completely free from anophelines. They slept during many months there at all seasons of the year in four different houses and never saw anophlines in their rooms—*Stegomyia,* of course in hordes. But a quarter to half-a-mile away it was very different; there anophelines were as thick as bees. What was the difference? The center of Freetown was in fact a town with large stone houses, open streets, and moderately well-arranged surface drains. But in the outskirts one comes to the streams, with their countless larvæ, in the back-waters and pools, and to the native huts, infested with anophelines, having therein a plentiful supply of blood. Why, then, should they fly abroad and visit the center of the town? In fact they did not, and the result is this important condition, that in the center of Freetown a quarter to half a mile from deadly centers of infection one has a segregated protected area, where the danger of contracting malaria is extremely remote. Again, by a series of observations they made in India they were able indirectly to come to somewhat similar conclusions. They sought to determine why, of a series of villages in the same district, one was highly malarious, another only slightly so, and they found that this was almost entirely dependent on the number of anophelines there present, and that the number of anophelines was dependent on another factor—the presence or absence of breeding grounds past or present; so that when a village was distant three-quarters of a mile from breeding grounds the amount of malaria—the endemic index as we termed it—was reduced to very low dimensions—5 per cent. or 0 per cent., instead of 50 to 70 per cent. where breeding grounds surrounded the native huts. They concluded from these observations that a distance of about a mile from breeding grounds was sufficient to protect that village from malaria, consequently that here at all events this distance was beyond the normal flight of anophelines. The distance in Freetown was decidedly less than this, a quarter to half a mile. These observations seemed to them of some importance as indicating the distance that sufficed to give protection from mosquitoes, or at least a considerable if not an absolute degree of protection. This question of flight of course requires still further study, since, as we shall see later, under certain conditions it may be a complicated one, resulting in distances as great as one to two miles being traversed. One sees, then, that various

problems still exist for a more complete solution than they were able to give in the time at our disposal, and that these problems have considerable bearing on the question of prophylaxis, and that the prophylaxis of malaria will not be best achieved by blindly proceeding to act against mosquitoes as a whole, but by careful action based upon accurate study of all the habits of mosquitoes. Dr. Stephens unduly prolonged these preliminary considerations, but their importance is in his opinion immense, and they are at present practically completely neglected.

Prophylaxis.—In the remaining portion of his paper he considered very briefly modes of prophylaxis, pointing out what in his opinion are the merits or demerits of each system. For in fact it would appear from the advocates of these systems that one and only one method exists—that is, the one advocated by the particular person. Thus it seems to be the aim of the advocates of each system to decry that of others. This does not appear to be the best solution of the problem, for that method that may succeed in one place may quite conceivably fail in another where the conditions are entirely different.

The measures usually adopted are:

1. *Antilarval.*—Of this method it appears to be fundamental and thorough, provided it takes the form of systematic drainage, and that it is the method which should as a sanitary reform be followed as a steady continuous policy. Its merits consist in the obvious fact that as the mosquito breeds in water, if this water can be drained away, the number of larvæ in that area must diminish, and probably if there is no influx from without the number of mosquitoes, and probably also of malaria. It seemed to him that this method should take from the first this form—namely, drainage—and that it is not wise to substitute for it petrolage except as a temporary makeshift, without any attempt to diminish the real source of the mosquitoes—namely, the water.

2. Mechanical prophylaxis by wire netting, etc. That by this means excellent results can be got those of the Italians show. The Japanese have likewise applied it to their troops, with the remarkable result that in a particular regiment the entries diminished from 2,000 odd in 1900 to 256 in the first six months of 1903. We are told that the sentries wore veils and gloves at night!

3. With regard to quinine. He believes this method, too, excellent, and the success attending it remarkable. How far applicable in every locality local conditions must decide. He believes its applicability is somewhat limited, but this should not hinder its adoption in suitable circumstances. In many isolated villages he believes malaria could readily be stamped out in this way, where antilarval measures would be impossible owing to the fact that the larvæ breed in the rice swamps surrounding the villages. A quinine prophylaxis among Europeans in small settlements has given in the hands of the Germans excellent results. The so-called gram prophylaxis, repeated on two consecutive days, has in certain instances been thoroughly effective, and it should be noted that there is no danger of the quinine producing blackwater fever, for, on the contrary, it is among those insufficiently protected with small doses—that is, among those suffering from malaria—that quinine induces blackwater fever.

4. Next, he called attention to a mode of prophylaxis—namely, "segregation of Europeans." It was, however, recommended by Ross as "one of the fundamental principles which the State must adopt in order to extirpate malaria in tropical cities." Major Ross has informed him personally, however, that this was done on general sanitary ground, only, and not on the special grounds resulting from the demonstration by Christophers and myself that the natives were the source of European infection in the tropics. He thinks, then, that they may claim in their report to the Royal Society of May, 1900, to have first put forward this as a definite prophylactic measure based upon our knowledge of how Europeans are infected. Manson has also declared segregation to be the first law of hygiene for the Europeans in the tropics. Dr. Stephens is led to advocate this measure with all the scriousness and urgency he could, because he had seen for himself during two years' traveling in British possessions in Africa the terrible effects resulting from its neglect. That it was a practical policy he had no doubt. He had, in fact, seen it carried out—on general grounds—in Accra, where most of the officials enjoy the protection of well isolated bungalows well separated from the unsanitary native huts; unsanitary in a very special sense, for it is here that anophelines are infected. He had seen that the segregation of Government House, Freetown, a quarter of a mile from native huts, afforded complete protection. It is a policy that can be carried out in the case of single bungalows, situated in the bush, in larger settlements, and even eventually in towns. And yet an African Governor has denounced it as academical (although actually in existence in Accra), impolitic, and so forth. That it is not so is shown by the fact that another African and unprejudiced Governor, who had no system of his own, has actually carried out this prophylactic method, and, personally, he rejoices to learn that in several Gold Coast stations the Europeans now enjoy segregated cantonments. The principle, in fact, in its widest application is that we see over the whole of India, namely, European cantonment and native bazaar. In its more limited and still easier application it means that the European bungalows should not be built as now, in the midst of a native village, surrounded by huts, swarming with infected anophelines, but that an isolated site some half-mile away should be chosen. He believes the immunity then given to Europeans living hitherto in the midst of infected anophelines will be very great. It was an urgent matter and one easily carried out, and one that would at once save many lives, while measures for draining large towns would be a matter of many years. But it is also said that it is not a just method, for the native is neglected, the native must be treated as the white man. Within limits this is true, but it is the limits that alter the nature of the case. When the sanitary and general education of the native population has made any progress whatever, it will then, perhaps, be possible to begin to treat natives and Europeans alike; but until that happy day arrives it is not right to sacrifice European lives that are daily sacrificed to such false sentimental ideas.

The Success of Mosquito Destruction Operations.—Captain S. P. James, I.M.S.; and Lieutenant S. R. Christopher, I.M.S., read this paper. They said so many operations where mosquito destruction has been successfully carried out are reported that it appears almost unnecessary to ask how far such measures may be considered of practical utility in diminishing the incidence of malaria. It is, indeed, only when one makes a closer study of the reports of operations that one realizes in how many cases little or no proof of success is given, and in how many conclusion of success is based on such inconclusive evidence as the number of admissions to hospital and popular report. As regards the number of breeding places it is necessary to

destroy in order to bring about a successful result, we find curiously optimistic ideas very prevalent, and it is far from unusual to see a reduction in admission rates put down to the most trivial and inadequate operations. In perusing such accounts one finds it very difficult to reconcile these easy and triumphant successes with the extreme difficulty encountered in their own efforts. The operations undertaken by the Government of India at Mian Mir were throughout very thorough. Every effort was made to make the destruction of breeding places complete, and experiments were continued for over two years. Many hundreds of pools were drained or filled, and throughout the whole area systematic search for and destruction of breeding places was consistently carried out. Here, then, if mosquito destruction is so readily brought about as would seem from so many accounts, one should have been able to show a very marked and decided reduction in the number of adult *Anopheles* and malaria. As a matter of fact the result in both cases was poor and totally out of proportion to the means employed. If adults were reduced in number it was demonstrable only in the first four or five weeks of the rains with the onset of which the fever season begins. Later on in the season it only required the care always necessary for the detection of *Anopheles* to make it very obvious that marvelously little reduction in their numbers had taken place. The effect upon malaria consited in the delay of the onset of the fever season from the end of August to the end of September. In October the most strenuous and apparently complete measures against breeding places seemed not to influence malaria either in the bazaars or among the troops.

To what are they to ascribe the absence of the usual successful issue? They do not feel justified in considering it due to want of thoroughness in the conduct of the operations nor to peculiar conditions in Mian Mir. There is little doubt that the difference is entirely due to the great disparity in the value of the tests used in estimating the reality of results achieved. In very few instances has an attempt been made to verify a reduction in the number of adult *Anopheles;* nor has a reduction in endemic malaria, as shown by the number of infected natives, ever been demonstrated. The endemic index of Freetown approaches 100 per cent. If measures really possess the success claimed for them it should not be difficult to reduce this to 50 per cent. or less. Short of a reduction in this percentage infection they cannot claim a success in the reduction of malaria. In their reports on the experiment at Mian Mir they attempted to give some idea of the determinable effect of the operations, and succeeded in actually demonstrating such effect, though it was but partial.

Their attempts to really show what has been the effect of operations have a distinct value. They show that destruction of *Anopheles* sufficiently complete to be of practical importance as a prophylactic measure in an undertaking much in excess of the usual estimate of the character of operations necessary. Perhaps the most valuable result of the Mian Mir operations was that they gave an insight into the difficulties which are almost certainly to be encounterd in most really malarious places. They found *Anopheles* breeding places much more numerous than would be gathered from most accounts of operations, and the difficulty of keeping up with the everchanging situation of breeding places under different degrees of rainfall was very great. They found that they had to deal with breeding places under different degrees of rainfall was very destruction was utterly futile. They encountered enormous changes in the facilities for breeding places in the rains, and had to count upon, what appears to have been the main factor causing our want of success, an infiltration of adults from outside the area which could not be prevented by any means in their power. In chronicling their want of ready success we fully realize the inadvisability of damping enterprise by the suggestion of possible failure. But if in the near future they are really to reduce malaria in the tropical possessions, something more must be done than merely to popularize the idea of anti-malarial measures. That malaria will be reduced and in a manner much more direct than by blind schemes of drainage, there is no reason to doubt. Little good, however, seems likely to result from proclaiming a successful issue, the evidence for which will not bear criticism.

Before concluding they called attention to certain points which seem to us of importance. (1) It is easy enough to destroy larvæ in millions and to do away with hundreds of breeding places. It by no means follows that malaria is diminished or adult *Anopheles* banished, and the success of operations on a large scale is still very doubtful. (2) The idea that by destroying breeding places around a barracks, prison, or other building, a reduction in malaria is likely to result requires more critical work before it can be accepted. (3) The occasionally-reported results where a brigade has rid a town of malaria they have no hesitation in challenging as absurd. They are by no means so certain that the number of *Culex* and *Stegomyia* may not be very considerably affected by such means. (4) The use of "admission returns" of all kinds as evidence is a miserable method of proof, and the insignificant factors which greatly influence all such figures make them quite valueless for the purpose of estimating the effect of operations. The only really satisfactory test of success is a reduction of the endemic percentage of infection. In this connection they recommend isolated bazaars and villages as more suitable in the present state of our knowledge for trial experiments than large tropical towns. (5) In any attempt to show a reduction in the number of *Anopheles* it is necessary to recognize that it is easy to delude oneself with their apparent absence, since they are always difficult of detection, and, except in certain places and in certain times of the year, would, as a rule, be considered absent by an observer imperfectly acquainted with their habits. (6) Mosquito operations reports are often extremely uncritical and often ridiculous, since they claim an amount of success for which they have no evidence.

THE SURGICAL PHYSIOLOGY OF THE LYMPHATIC SYSTEM.

BY C. H. MAYO, M.D.,

OF ROCHESTER, MINN.;

SURGEON TO ST. MARY'S HOSPITAL.

A STUDY of the lymphatic system readily explains many physiological as well as pathological processes. The great part played by the absorbents in maintaining the nutrition, repair and defense of the system has apparently received but little attention as compared with its importance. That the greater part of the absorption of the body, excepting the intestinal, is accomplished by the lymphatics, is well understood; but their direct relation to surgery seems to have been but occasionally appreciated.

The lymph system, consisting of vessels, channels, spaces and glands, accompanies the arterial system, but varies greatly in extent and character, according to location. These vessels drain certain definite areas, and when diseased by infection, it is usually possible to locate the point of its entrance. The lymphatic is a closed system, having capillaries ending in connective tissue spaces, and the vessel walls, while resembling veins, are exceedingly thin. When we consider that all the tissues of the body are more or less bathed with lymph, a fluid derived from and almost similar to the blood plasma, we would expect to find, as is the case, that tissues will be supplied with lymph and absorbents in direct proportion to their exposure and necessity for repair, as well as to their activity.

Interspersed in the course of the lymph vessels are found groups of glands. These organs vary from the size of a pin head to that of a large bean, and serve from their structure to act as filters to all the fluid passed through them. The glands are filled with nests of the forming leucocytes, and all the lymph is exposed to the probable purifying action of these cells. Here it is that the great bulk of bacteria is checked in infection, and through the action of the leucocytes or some unknown physiological chemistry only the toxins and a limited number of bacteria are permitted to pass to the venous system. It is here that the cancer cell is checked and later overpowers the gland and develops in its outer layers; so one gland after another takes up the work of protection by preventing the waste cells, the products of metabolism, of nutrition, repair or infection, from entering the blood unchanged. Leucocytosis then, to a great extent, will depend largely upon the region involved in inflammation as well as the intervening gland and lymph area between it and the circulation.

An enlarged gland is then an evidence of a local struggle or of a defeat, and it is this type of gland tumor usually considered in surgery. The great number of battles won are an unknown condition; therefore, there is the less appreciation of their work. Manfrid, in an examination of 88 animals and three men who had died of non-infectious diseases, found infected glands in 78 of the animals and all of the men. The glands grouped in the neck in large numbers, as about the mouth, nose and trachea are so many possible points for the invasion of bacteria. Other glandular aggregations are placed on the flexar and vessel side of the union of the extremities with the body, while the interior of the thorax and abdomen is freely supplied with such organs of chemistry and defense. It is claimed that the glands are capable (after removal) of reformation by development at the union of new lymphatic vessels, as the cells found and the reticulated structure and capsule are all capable of regeneration in these glandular regions. For this reason we must, if possible, destroy the original focus when glands are removed for infection.

In certain cases where the glands and lymphatic area are so thoroughly removed that the return of the lymph to the circulation is nearly abolished, a peculiar condition of lymph edema of the limb develops and remains until the equilibrium of the circulation is re-established. This is noticed not infrequently in cases of complete operation for cancer of the breast, where the arm may remain in such a condition for a considerable period. For a long time it was thought that there were but two lymph ducts of entrance into the circulation. The right lymphatic duct opening into the right subclavian vein receives absorbents from the upper right half of the chest and thorax, also the right upper extremity and side of the neck and head. The left or thoracic duct empties into the commencement of the left innominate vein and drains, or has been supposed to drain, all the rest of the body. Leaf has recently found that there may be a communication between the lymphatics and small veins in the groin, and it is possible that others exist and will eventually be located. The nutrition of the body is maintained by absorption of water and digested food, nearly all of which is taken directly into the circulation of the intestine, after passing the epithelial cell. By some wonderful chemistry this cell transforms this material into a suitable condition for association with the blood. The fats are unable to pass the barrier and with the products of metabolism, in maintaining the chemistry of the absorbing cells, enters the circulation by the way of the chyle ducts.

It is now generally considered that the ductless

glands are drained by the lymphatics. When we think of the great importance and the intense and sudden effects of the secretion of these glands when given to the system, we can see the benefits of an intricate duct system, while the failure to drain certain alveoli may partially explain the development of peculiar types of retention cysts, as in colloid cystic goiter. The hard dry gland often found in exophthalmic goiter and the extreme symptoms of Graves's disease, many of which may be produced by thyroid feeding, may possibly be in part from excess of drainage.

The lymph fluid being of nearly the same density as the blood, there can not be expected to be any great osmotic action into the circulation, although the ready absorption of solutions injected into the tissues is explained by direct endosmosis as well as by lymphatic absorption. The quantity of lymph depends upon the pressure in the capillaries and the permeability of its walls, while its circulation depends upon muscular action, the respiration and the heart.

The causes of inflammation are from thermal, mechanical or toxic irritation, the last including the chemical changes caused by bacteria. Some authors would limit the term inflammation to the infected cases only, calling the changes incident to other forms of irritation reparative processes. From one or more of these agents acting through the local nerve supply, there occurs a dilatation of the local arteries, veins and capillaries, followed by an increased rapidity of the circulation which soon slows, and the white cells adhere to the endothelial layer and pass between these cells to become the leucocytes in the surrounding tissue. More severe irritation, and the plasma exudes, still more severe, and there is a free escape of blood cells and fibrin, and the exudate is now capable of coagulation.

Exudates are known from their quality as serous, fibrinous, croupous, diphtheritic, hemorrhagic or suppurative. Serous exudates follow irritation, and also occur in passive congestion and venous stasis. As represented by forms of eczema, anasarca of advanced cardiac or renal disease and the ascites of obstructed portal circulation. The exuded fluids may become inoculated with bacteria in open wounds, or bacteria may make an exudate from the irritating power of the toxins, and the peptonizing power of the bacteria. This fluid is known as pus, and consists of the plasma with white corpuscles and the fixed tissue cells converted into pus cells, with the bacteria peculiar to the infection. In fresh wounds, there is an escape of a bloody, serous, albuminous fluid from the divided tissues, lymph spaces and capillaries. This fluid distends the tissues and separates the injured surfaces, preventing or delaying healing, and being highly albuminous, is subject to infection and decomposition. It is to relieve the tissues of these fluids that external drainage is established. The result of considering drainage as being the delivery in all cases of exudates to the surface is the probable explanation of why each operator has developed a system from his own experience with reference to this subject.

The changes found in special organs are most marked. The brain, in which we would not expect much cell change or repair, is filled with lymph spaces; but is very deficient in lymphatics, the subarchnoid space serving as the absorbing area on its surface. In its substance we will often have a hemorrhagic exudate remain as a local collection, then, by means of secondary changes of the blood cells and a deposit of fibrin and albumin, there is developed a surrounding wall and the exudate is now a cyst, the change sometimes requiring but a few weeks, sometimes months. Injuries of the skull and brain develop cystoid scars as a result of adhesion of the membranes and shutting off of the arachnoid space, while inflammatory diseases, unless involving the surface, may cause no change in temperature and, like cysts, will be located principally by pressure symptoms. It is well known that abscesses may remain for long periods in the substance of the brain without marked symptoms.

The liver and kidney are peculiar gland structures in which the excretory ducts can to a certain extent supply the place of lymphatics in ridding the organ of the products of metabolism. In these organs there is a deficient lymph circulation in their structure, yet a free one upon their surface, and at the region of blood supply. The symptoms of inflammation will be somewhat like those in the brain, yet less marked. Inflammation near the surface causes marked disturbances, especially should perforation of the capsule occur, and a greater field for absorption be invaded. The skin is filled with lymph vessels, constant repair and protection being necessary.

The lungs are rich in lymphatics, and infections or toxins are early and constantly delivered into the circulation with the resulting reaction of fever. The onset of infections in regions rich in absorbents, as the lung, neck, axilla or groin, is often marked by a chill to be followed by continued temperature during the infection until reaction develops protective granulation. Repeated chills occur in regions in which accumulated products of infection is delivered at intervals into the venous circulation without the intervention of the lymph system, as in sinuses of the brain, liver, bone, marrow, uterus or prostate, and occur in streptococcus poisoning where the edema and induration may cause veins to open as sinuses, or when local foci of infection occur in the circulatory system itself.

The peritoneum is but little less in area than that of the entire skin covering of the body. Its lymphatic system is most active in the upper portion of the abdomen. The lymph vessels of the peritoneum over the small intestine are numerous, while there are a few in that portion covering the large intestine, which is capable of but little absorption, as is the parietal or pelvic layer. The peritoneum covering the colon is exudative, and over the small intestine absorptive, not considering the lacteals of the mucous membrane.

The fundus of all organs is deficient in lymphatics, hence acute obstruction gives cyst formation, and chronic inflammation causes shrinking and thickening of the organ. Against infection the body has a certain degree of resistance in the blood. Fresh blood is germicidal to some extent, and later is also a culture medium from the contained albumin. It is increasingly germicidal at a temperature from 100° to as high as 104° F., rapidly losing it thereafter with increasing heat. The plasma free from albumin is more strongly germicidal than the blood. There is a continuous absorption of all exudates in regions supplied with lymphatics and in infectious diseases due to a carrying to the circulation of toxins and at times bacteria, and as a result of increased tissue metabolism, there is a rise of temperature. From repeated infections, the system may become nearly or quite immune to reactionary disturbances, and local infections long retained lose their virulence through a type of continuous inoculation by absorption in minute dose, and through the death or loss of virulence of the bacteria.

If this view of the action of the lymphatic system is correct in outline, it affords additional light upon some obscure pathological conditions. Certain organs are subject to cysts and the same ones, also, to sclerosis; we find that they are the organs with a deficient absorbent system. In theory then, a chronic excess of diffusion would be followed by connective tissue due to the chronic irritation. This would be most marked in the proximity of the vessel. Acute hemorrhage may not be absorbed and by natural changes produce cysts.

Considered in this relation to malignant disease, the condition of the lymphatic system is of the utmost importance. In fact, practically all the advancement in the modern surgery of cancer has been through a study of the areas of lymph distribution involved in any malignant focus. We now have definite gland fascia areas, which must be removed with or at the time of the removal of the original malignant growth. This is true of internal as well as external deposits. It is usually said of cancer that early operation gives a good prospect of cure.

This may be modified by the conditions or age or lymph circulation in the area involved. Thus, cancer in the young is rapidly fatal and early recurrence of metastasis frequently follows operation, the gland distribution being early involved. As compared with the young, old age with its disappearing lymph system and late operation, rather than early time alone considered, may often be more favorable for permanent recovery.

Cancer statistics as to cure improve with each decade of life, other conditions being equal.

Varieties of Drain and Drainage Adjuncts.—First is rest by splints, pressure dressing or bed, to quiet the circulation. Second, by elevation to reduce arterial supply and favor venous and lymphatic return. Third, by massage to break up coagulated exudates and enable the lymph vessels to remove the exuded material. A good masseur, for instance, will relieve the ecchymosis and swelling of a black eye in a remarkably short time by massage and rest. Fourth, moist dressings favor escape of the exudate from open wounds and also favors the lymphatic circulation in closed injuries. Fifth, adjuncts to drainage in the use of solutions having affinity for moisture acting by osmosis as glycerin or alcohol. Sixth, wound drainage is accomplished by the open method with or without secondary suture. Seventh, by separate incision. Eighth, by wicks, capillary or tubular drains or gauze packs as mechanical aids.

Capillary drains are of catgut, hair or silkworm gut in bundles, and serve to drain serum of small amounts in small or large wounds where prolonged aseptic drainage is required, as after gland removal. Capillary drainage is not sufficiently free for the drainage of pus. Tubular drains deliver freely all wound secretions and in aseptic cases, should serve their purpose in from twenty-four to forty-eight hours. When of rubber they should be split from end to end instead of perforated, as it is more flexible with less danger from pressure, drains at all its length, and is easily removed. By means of a thread attached to the tube it may be taken out without removal of the dressing. In septic cases, the tubular drain should be left until the wound is lined with granulation tissue and is without pockets or accessory cavities, as granulation tissue is the natural protection of the system against absorption, as well as being a reparative process.

To freely drain the general peritoneum, nothing seems better than glass, as lymph adhesions form slowly about its surface, and a large area is thus brought under its influence. Gauze is peculiar in its action, at first being a capillary drain; later its meshes become choked with fibrin and it no longer has capillarity, therefore it should not tightly fill the opening from which it emerges. It is a great developer of granulation, as it strains out the blood cells and fibrin from the serum, thus holding in apposition to the cut tissues elements necessary to the development of granulation. Tube drains carry away the same material and granulation will be slower. It is this peculiar action of gauze which makes it necessary to leave it without disturbance for at least four to six days. Previous meddling will tear open the young granulations, give fresh injury, open lymph spaces, and in clean or septic cases it is usually a cause of rise of temperature. Gauze is used in draining acute injury of the brain and in the quarantining of acute infections of the peritoneum. Aseptic operations are frequently followed by a from one to three degrees rise in temperature within from thirty-four to thirty-six hours, which is caused by absorption of blood and is a ferment fever. Temporary fever later than this may be from the intestines, but if this temperature continues, the wound should be examined.

We may say, then, that aseptic operations in regions rich in lymphatics, where the lymph circulation is but little disturbed, will not require drainage—as ligation of vessels in the neck, Alexander's operation, and hernias in the inguinal region. We may also say that aseptic operations in these regions in which the lymph system is removed require capillary drainage from four to six days, as auto-drainage is temporarily abolished and early removal results in serous accumulations without increase of temperature usually discovered when the cases should be dismissed from care; as in removal of cervical glands, cancer of the breast and auxiliary glands, and malignant disease of testicle and inguinal glands. Free drainage of the stump should be employed in amputation for malignant disease where the glands are removed from axillary or inguinal regions.

In regions rich in lymphatics, where operations, for septic conditions, must be made, we open fresh area for absorption of toxins and our endeavor should be to use upon the incised surface strong antiseptics, such as carbolic acid followed by alcohol, chloride or lime as a caustic, or in mild cases glycerin, to prevent or inhibit the action of absorbents, and maintain the disease as a local infection. This is markedly shown in operations for the removal of bone necrosis. For the same reason the cautery is used to incise abscesses in certain regions, and also to make puncture drains in cellular streptococcus poisoning.

Iridectomy and scleropuncture in glaucoma substitute one set of lymphatics for another. In operations for the relief of increasing spina bifida, we employ a suture of two strands of silkworm gut, or catgut can be passed through the stump of the scar to temporarily deliver the spinal fluid into the tissues of the back. Experimental work is now being conducted with a view of permanently draining forms of hydrocephalus into the rich lymph system of the cervical region. In the drainage of wounds, it is a good rule to make a separate incision at the most favorable point and close the original operative wound completely. This plan will improve the scar, and in large abdominal incisions will very often avoid hernia.

In aseptic operations of the abdomen involving considerable bruising or denuding of the peritoneum, the pelvis should be elevated by raising the foot of the bed, the gravity acting as an aid to auto-drainage, the peritoneum being capable of absorbing from three to eight per cent. of the body-weight in an hour.

In septic diseases, just the opposite condition is desired to secure drainage and maintain the condition as a local one, by elevating the head of the bed and also elevating the upper extremity of the patient to gravitate to the pelvis, where delivery may be made through glass tubes. This method is used in diffuse peritonitis. The diseased or septic focus should also be quarantined by a gauze pack through a separate incision, should the condition of the patient warrant the increased operative interference.

A CONTRIBUTION TO THE STUDY OF INFECTIONS OF THE PROSTATE FROM THE URETHRA.[1]

BY FREDERIC BIERHOFF, M.D.,
OF NEW YORK.

While it may be confidently stated that since the more general adoption of the antiseptic plan of treatment of gonorrhea, the percentage of those cases in which an extension of the infection to the posterior urethra and prostate occurs has been greatly diminished, still this extension of the infection does occur, in a fairly large percentage of the cases of gonorrheal urethritis, in spite of the most careful treatment along the most modern and approved lines.

I exclude, of course, those cases in which instrumentation has been employed, such as the passage of sounds, catheters, etc., and those in which injections of the purely astringent drugs have formed the treatment. Why this extension of the process (even where the infection runs a mild course) should occur, sometimes even in the earliest days of the gonorrhea, and why, when it does occur, it should, in the greater number of the cases run so mild, or subacute a course, even when the actual invasion of the posterior urethra has been accompanied by acute symptoms, are questions which have occupied my attention for the past few years, and if I present the result of my observations to you to-day, it is in the hope that these findings may serve, perhaps, as a spur to others, to look more deeply into these questions than lies in my power to do.

Of recent years the view of Guyon and his scholars that the compressor urethræ form a barrier against the advances of the gonorrheal process, has been denied by competent observers, such as Diday, Fürbringer, v. Zeissl, Aubert, Eraud and others. Finger believes that the gonococci have a tendency to locate in the glandular adnexa of the urethral mucosa, and there to form their principal foci of infection; that the infection spreads along the mucous membrane, from follicle to follicle, as far as the membrane contains follicles, and comes to a halt when it reaches a part which is poor in them. Thus the process tends to spread until it reaches the pars membranacea, which has no follicles and is poor in glands, and he believes that an external provocation is required to cause the gonococci to extend over the pars membranacea to the pars prostatica, which again contains numerous gland orifices, the glandulæ prostaticæ, about the caput gallinaginis.

I believe Finger's explanation to be correct, since careful endoscopic examinations have shown me that almost all chronic anterior gonorrheas have their seat in the glands and lacunæ, and the tissues immediately surrounding them, and since examinations of cases of posterior urethritis have shown me that, in almost every case, infection of the posterior urethra was equivalent to infection of the prostate.

[1] Read at the Third Annual Meeting of the American Urological Association, Atlantic City, June 9, 1904.

We have, therefore, to look for the causes, or conditions, which, in the absence of external insults (which we all recognize as potent factors in causing an extension of the infection to the posterior urethra), and in the face of careful treatment with the gonococcicide drugs, permit the infection to spread over the pars membranacea to the pars prostatica.

If we examine the urethra in individuals presenting no symptoms referable to the genito-urinary organs, we find, in a fair proportion of the cases, hypersensitiveness and a distinct degree of congestion of the mucous membrane of the entire posterior urethra; upon palpating the prostate, in these cases, we also find moderate enlargement of the gland, with areas of softening. The prostatic secretion is somewhat increased in quantity, and thinner, and more watery than the normal, and shows, under the microscope, fewer of the normal prostatic elements. In other words, it is increased in quantity, but diluted. Furthermore, if we examine patients who, never having had gonorrhea, or, having had it and been cured of it, complain of symptoms referable to the genito-urinary organs—the so-called "sexual neurasthenics"—we usually find an even more decidedly exaggerated sensitiveness and congestion of the posterior urethra, with similar, although more pronounced, evidences of prostatic congestion.

In other words, a large number of males who do not suffer from gonorrheal urethritis present evidences of a mild, chronic congestion of the posterior urethra and prostate, conditions which distinctly favor the extension of any urethral infection to the congested parts. If you will bear in mind the facts that the gonococcal infection spreads, by the rapid reproduction of the germ, *upon the surface* of the mucous membrane (and then between the cylindrical epithelial cells), and that anything which favors the congestion of the membrane fosters the rapid spread of the infection, I believe that the cause of this spread to the posterior urethra and prostate will be explained, at least for a large proportion of the cases. Excesses in venery, the use of alcoholics, sitting for long periods, horseback or bicycle riding, etc., favor the spread of the infection to the prostate by causing a similar congestion of the posterior urethra and prostate gland.

I believe this view was first advanced by me, in an article in the Medical News, of December 28, 1901. Others have since agreed with me. Since then I have continued the examinations then referred to, and have had no cause to change my views; on the contrary, I have only had that belief strengthened.

The exciting causes which have brought about this congestion of the deep urethra and prostate, in the cases which I have examined, have been masturbation (in the younger patients and many of the neurasthenics), protracted indulgence in withdrawal, coitus interruptus, sexual excesses, or perverted indulgences, and long-continued sedentary occupations. The last-mentioned I have frequently found, in dispensary patients, especially machine operators, to be the cause of a slight, mucous discharge, accompanied in patients of a neurotic type, by ill-defined, deep-seated urethral pain, dull, heavy, lumbar dragging, precipitate, or nocturnal emissions, constipation, etc.

I believe that you will agree with me that most cases of gonorrheal prostatic infection run a comparatively mild course, and are of the catarrhal (endoglandular), or the follicular type, and that a large part of the cases of the parenchymatous type can be cured without incision. Certainly, this has been my experience with my cases, both in private and dispensary practice. Why the course of a prostatic gonorrhea should, in the majority of cases, be so mild, when compared to the urethral inflammation, and why, so long as there be no reinfection of the urethra, the prostatic involvement should give so few symptoms, are questions which have long interested me.

If the prostatic ducts were lined with pavement epithelium, I should say that it is the natural resistance of the squamous cells to the invasion of the gonococcus which protects the gland from the encroachment of the germs; but, according to Krause and Langerhans, they are lined with cylindrical epithelium, which, in itself, offers but little resistance to the spread of this infection. So we must look elsewhere for the cause.

This, I believe, is to be found in the naturally alkaline reaction of the prostatic fluid. Although some authors refer to it as being faintly acid, or neutral in reaction, I have found that, in almost all cases, whether in patients presenting no symptoms referable to the gland, or in those with prostatic congestion, or inflammation, the reaction was *alkaline*, and in only isolated instances was it neutral, or very faintly acid, and then not persistently so.

A few years ago I attempted, in a series of cases, to cultivate, upon serum-agar, the gonococcus obtained in the secretion of infected prostates. To my great disgust, I was unable to do so, in a single instance. After careful control of the culture-media, etc., I communicated the facts to my chief, Dr. Frank, who referred the question to Dr. Wassermann, and was told that the gonococcus can only be cultivated with difficulty from the prostatic secretion. Similarly, Finger, Ghon, and Schlagenhaufer report that the gonococcus grows but *poorly* on serum-agar of *high alkalescence*, better upon this culture-medium when a little acid sodium phosphate has been added, and *very well* upon an *acid medium*. And the prostatic secretion is usually of a *decidedly alkaline* reaction.

Unfortunately, I have been unable of late to carry on culture experiments along this line; but I feel that the fact that the gonococci which enter the prostatic ducts are *brought into and kept in constant contact with a secretion of a distinctly*

alkaline reaction, may be the explanation of the generally mild character of gonorrheal prostatic infection, through a temporary inhibition of the power of development of the germs. In other words, I believe that the character of the prostatic secretion forms a natural protection, even if only partial, against the involvement of the gland itself. I advance this view simply as a *theory,* in the hope that further study and experiments may, at some future date, allow me to speak definitely upon the topic.

When gonorrheal infection of the prostate occurs, it does so in one of three forms, viz., the endoglandular, or catarrhal type, the follicular and the parenchymatous.

In the first the gonococci do not penetrate deeply into the subepithelial layers, but lie upon the surface, or between the cells. In the cases of this type which are seen early, there may be little or no change in the urine, and few or no symptoms, unless the onset be acute. The onset is, however, in this, as in the other forms of gonorrheal prostatitis, usually of a subacute, creeping character, and is apt to altogether escape the patient's notice.

The prostate is found, on examination, to be changed in size and consistence, although in the mild superficial type, the changes may be so slight as to be hardly palpable, and to be only a very slight, uniform enlargement and softening. As the degree of severity of the process increases the enlargement is more pronounced; the softening is, however, of the same character as before, and the prostate feels "doughy." The quantity of prostatic secretion is usually abnormally large; its microscopic appearance may be normal, or more watery than usual. Under the microscope it is found to contain fewer of the lecithin granules than the normal, more mucus, few leucocytes (where the process is purely superficial), and gonococci, usually extracellular. Where the germs have penetrated deeper, there is a yellowish tinge to the secretion, with a degree of opacity, the color and opacity varying in depth according to the severity of the process. Microscopically the pus cells are found to be much more numerous, and numbers of them contain gonococci.

Under appropriate treatment, which is usually in cases of this type, not of long duration, the enlargement and softening gradually disappear, the leucocytes diminish in number, as do the gonococci, finally disappearing entirely—the germs usually an appreciable length of time before the pus cells. In the later stages, epithelia appear in the secretion, but also gradually diminish in number and disappear, and the entire character of the secretion gradually becomes normal.

The second variety, the follicular, represents the condition in which the gonococci have penetrated into the subepithelial tissues, and there keep up a mild degree of inflammation. Owing to this perilobular, productive inflammation, the affected lobules gradually become surrounded by a layer or sheath of infiltration, which imparts a sensation harder than the normal prostatic tissues, to the examining finger. In other words, we feel *areas of hardening* in the gland. Where the duct, or outlet of a lobule is involved to such an extent that it is completely occluded, this sensation is most pronounced. The second urine is cloudy, usually distinctly so. It is the follicular type of prostatitis which gives us those chronic cases which give a history of having persisted for months, or even years, and it is at times necessary to examine the secretion several times after massage of the prostate, when the older cases are first seen, before one can discover gonoccoci in the secretion; it is this form, too, which gives us the seeming relapses, when, after the gonococci have been absent for days and the urine clear, there is a sudden reappearance of turbid urine, with pus and gonococci in the prostatic secretion, following massage, or the provocative tests.

I have repeatedly experienced this sudden return in the treatment of cases of this type, and it is due to the rupture and emptying of the contents of a previously occluded, diseased lobule. Continuance of the treatment is followed by a rapid subsidence of the symptoms. In this type of cases also it is frequently necessary to resort to the application of heat to the prostate, through the rectal psychrophore, in order to aid in softening the areas of hardening, and to make it possible to express the diseased secretion.

Both the aforementioned types of prostatitis begin usually without pronounced symptoms to mark the onset of prostatic involvement. The onset may, however, be of an acute character, with pronounced symptoms, such as frequent and painful micturition, followed by tenesmus. Seldom is there any chill, or febrile movement, or feeling of pain and heaviness in the perineum. These latter usually denote the onset of the acute form of the third, or parenchymatous, variety.

In the milder cases of parenchymatous prostatitis it is sometimes difficult to differentiate between this form and the moderately pronounced form of endoglandular prostatitis, especially when the latter occurs in neurotic individuals. But, whereas the enlargement of the prostate, in the latter cases, is of a *doughy,* soft character, in the former it is more uniform and elastic. The sensitiveness is, in the former, also more acute, and distinctly a *pain,* while the patients with the latter type usually speak of the examining fingers causing rather a *disagreeable* than a *painful* sensation. And while the expressed secretion, in the endoglandular variety, seems simply to be exaggerated in amount, and to contain more of the fluid elements, with a varying number of pus cells, that of the parenchymatous variety has a *reddish* tint, and is found to contain *erythrocytes* in large numbers.

In the pronounced form of the trouble, however, there is no difficulty in making the diagnosis. Usually of acute onset, there is a distinct

increase in the frequency of urination, accompanied by a burning pain, and followed by a marked degree of tenesmus. If the enlargement of the gland is at all pronounced, there is difficulty in urination, which, at times, even amounts to retention. There is a dull, dragging pain in the perineum and rectum, with distress and difficulty in defecation, leading at times to obstipation. The pain tends to extend to the glans penis, toward the hypogastrium and into the thighs and makes sitting, or standing, very difficult and painful. Chill and fever may occur, and usually denote active suppuration; but they may be absent, even in the face of a prostatic abscess. On palpation, the prostate, in the severer form of parenchymatous prostatitis, is found to be markedly enlarged (sometimes to three, or four times its natural volume), hard, and exquisitely painful to the touch. When suppuration supervenes, an area of softening develops at some point in the gland. When rupture of the abscess occurs, relief from the pain and sensitiveness is usually marked, and a distinctly depressible area marks the point of greatest tissue-destruction.

The question whether abscess formation in the prostate occurs as a result of pure, gonorrheal infection, or of mixed infection, is still an open one.

The prognosis is good, as a rule, and even the more stubborn cases of the follicular variety are definitely curable, if proper treatment be persisted in. Only in those cases where a prostatic abscess spreads to and involves the pelvic cellular tissue, or those in which the symptoms of systemic involvement are pronounced, does the prognosis become grave.

The treatment of gonorrheal prostatitis consists principally of careful massage of the affected gland, combined with irrigations with solutions of the gonococcicide drugs. In spite of the doubts cast by some upon the efficacy of massage in ridding the prostate completely of its diseased contents, I must maintain that, when *properly carried out*, this procedure makes it possible to gradually expel the infection completely. Naturally, when the infectious matter has been expressed into the urethra, it should at once be rendered innocuous, by means of a flushing of the entire urethra and bladder. Personally, I prefer to irrigate the entire canal both before and after the massage, whether for purposes of examination, or treatment, since I believe that, in this way, the chance of entrance of germs into the seminal ducts is greatly diminished.

In the milder form of endoglandular prostatitis, a few applications of this treatment usually suffice to definitely rid the gland of infection. In the follicular form, the treatment must be persisted in, and usually covers from four to eight weeks. Frequently, in these cases, it becomes necessary to resort to the application of heat to the prostate. This, applied nightly, I have found to be of great service in softening the hardened nodules, and rendering possible the more speedy evacuation of their contents.

Where the onset is acute, rest in bed, and appropriate diet are indicated,—but not a suspension of the irrigations, so long as we work entirely with the gonococcicide drugs. Here the use of heat is also of service (in the form of a hot sitz-bath), and is grateful to the patient. Where pain and tenesmus are marked, opium and belladonna, in the form of rectal suppositories, help to give relief. In the parenchymatous form, these measures are also indicated.

Contrary to the usual usage, I believe that febrile movement is not, *in itself*, a contra-indication to local treatment. I have frequently seen rapid defervescence follow the inauguration of these measures; naturally, they must be applied with the utmost gentleness. But where pain and tenesmus are so great, or are so much increased by the treatment as to weaken the patient, I believe in waiting until the acute stage subsides; after that, *begin local treatment as soon as possible*. And where massage is not well borne, at least the irrigations should be employed to repeatedly disinfect the surface of the mucous membrane and limit, so far as possible, the tendency of the disease to spread.

I am not, however, an advocate of long-continued, or heavy pressure in massage of the prostate. I have too frequently seen brusque, or strong massage followed, in a few hours, by an involvement of the neighboring organs. It should be *very gentle*, for a duration *not exceeding a minute*, and be rather a stroking pressure than a kneading of the gland.

When, in follicular prostatitis, an occluded follicle ruptures, we feel a softened depression at the point where the focus of hardening had previously existed. Gradually the surrounding zone of infiltration disappears, until the prostate again feels normal. Similarly, too, the breaking down of the tissue and formation of an abscess, in parenchymatous prostatitis, is marked by the appearance of an area of softening, in the inflamed gland. The majority of prostatic abscesses tend to discharge by opening into the prostatic urethra, consequently, in the majority of cases, a counter-opening is not necessary, and it is possible to cure them with massage and irrigations also. Where the process breaks through the capsule of the gland, and involves the pelvic connective tissue, the perineal incision should not be delayed.

I have been struck by the frequency with which patients suffering with prostatitis, of whatever type, complain of a variety of nervous symptoms, chief among which are marked mental depression and, in the endoglandular and chronic follicular cases, decided disturbances in the sexual functions. These symptoms give way rapidly upon an improvement in the prostatic condition, and usually disappear entirely upon the restoration of the prostate to the normal.

Frequently there exists, simultaneously, an infection of the glands and lacunae of the anterior urethra with the prostatic infection. In such cases no instrumentation should be employed un-

til *after* the cure of the prostatitis, and then only when combined with flushings of the urethra, as before mentioned, to avoid re-infection of the prostate.

For purposes of closer observation, I have made use only of my own private patients, who could be closely controlled. In all, 62 cases have come under my observation with a gonorrheal or a mixed infection of the prostate. In 54 of these the infection was present when the patients were first seen, while, in the remaining eight it developed during the course of urethritis, for which I was treating them. In two of these eight the neglect of local treatment by the patients themselves, coupled with severe bodily excitation, in all probability, permitted, or caused the infection to spread to the prostate; in one it was the result of similar neglect, coupled with prolonged railway travel; in one as an extension of a periurethral inflammation, which was present when the patient came to me, so that proper treatment could not at once be begun; in two as a result of prolonged sexual excitement; in two for no traceable cause.

Forty-seven cases were of the endoglandular type, eleven of the follicular, four of the parenchymatous, of which two were prostatic abscesses. The eight which developed while under my care, were all of the endoglandular form.

In 57 of the cases there was a pure gonococcus infection of the prostate present, in five a mixed infection. Of these latter, in one case of prostatic abscess, there was a large, plump bacillus present with the gonococcus; in another, a case of parenchymatous prostatitis complicated with cystitis, ureteritis and pyelonephritis, a large staphylococcus was found in addition to the gonococcus. In one endoglandular case a diplobacillus, in another of the same type a large staphylococcus, and in a third, complicated with cystitis, other bacteria, of a kind not noted, were present with the gonococci.

Five cases (four endoglandular, one prostatic abscess) were seen in consultation. Eleven (nine endoglandular, two follicular) withdrew from treatment. The remaining 46 cases were treated until the disease was at an end; of these 34 were of the endoglandular, nine of the follicular, and three of the parenchymatous type, of the last of which one was a prostatic abscess. All of the 46 were discharged cured, and it was possible to control 41 of them later, at different periods, and all were then found to be still free of gonococci, and with normal, aseptic prostatic secretion in spite of their return to their usual habits of life. The controlled comprised 30 of the endoglandular, eight of the follicular, and three of the parenchymatous type.

Complications were present in ten cases, when they entered treatment; epididymitis dextra in two cases, sinistra in three, sinistra complicated with acute funiculitis in one, cystitis in one, ureteritis and pyelonephritis in one, tendovaginitis in one, periurethritis in one.

Complications developed in 13 cases; they were epididymitis dextra in five, this in company with a Cowperitis in one, and epididymitis sinistra in seven. In all but two of these cases the complications were traceable to distinct causes, such as exposure to chilling, severe bodily exertion, railway travel, and sexual excitement. Of the two exceptions, one was a case of prostatic abscess, the other of acute follicular prostatitis, and it is likely that the massage was the exciting cause of the complication.

The duration of the cases from the time that treatment of the prostate was begun until the gonococci were definitely absent and the secretion normal, under the microscope, was, in the cases of the endoglandular type, as follows:

Under one week, in ten cases.
One to two weeks, in eight cases.
Two to three weeks in six cases.
Three to four weeks, in one case.
Four to five weeks, in one case.
Five to six weeks, in one case.
Six to seven weeks, in one case.
Seven to eight weeks, in two cases.
Nine to ten weeks, in two cases.
Twelve to thirteen weeks, in one case.
Fourteen to fifteen weeks, in one case.

In other words, 24 of the 34 cases were cured within three weeks.

In the follicular type the duration was:

Four to five weeks, in one case.
Six to seven weeks, in two cases.
Seven to eight weeks, in two cases.
Eight to nine weeks, in one case.
Nine to ten weeks, in one case.
Eleven to twelve weeks in one case.
Thirteen to fourteen weeks in one case.

The duration, then, of these cases, is longer than that of the endoglandular type.

Of the parenchymatous type, the duration was five to six weeks in one case; nine to ten weeks in another.

The prostatic abscess lasted eleven to twelve weeks before it could be pronounced cured.

THE USE OF ABSORBENT PAPER IN THE SERVICE OF PRACTICAL HEMATOLOGY.

BY T. W. TALLQVIST, M.D.,
OF HELSINGFORS, FINLAND;
LECTURER ON THE PRACTICE OF MEDICINE AT THE UNIVERSITY OF HELSINGFORS.

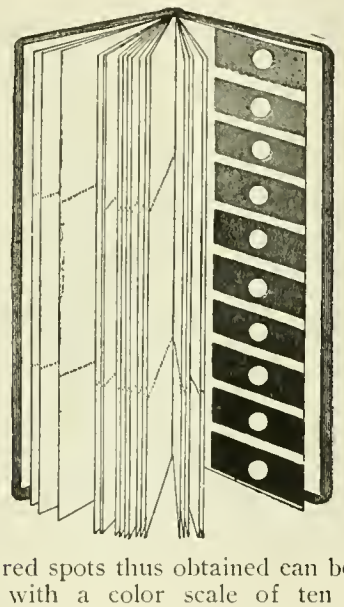
The great strides which research has made during the last decades in the department of hematological science has demonstrated the pre-eminent importance of a knowledge of the state of the blood in judging, not only of the genuine anemic conditions, but also of a number of other pathological circumstances. It has, therefore, become an imperative duty for the practising physician at all consultations on disease not to overlook the condition of the blood.

Here, however, we are confronted by a not inconsiderable difficulty. If every time an anemia or other pathological condition of the blood might be suspected to exist, we should set to

work with all the apparatus required for a minute examination of the blood, the consultation hour would assuredly not give time for many such scrutinies. Besides which, the expense of this apparatus would in many cases stand discouragingly in the way of the individual physician.

The presence or absence of anemia makes itself known above all in the quantity of the hemoglobin, and the first instrument needed is certainly, under such circumstances, a practical and easily applied hemometer.

The "*hemoglobinscale*," constructed by myself some years ago, can, in this respect, scarcely be excelled as regards simplicity in application, and the widespread favor which has already been won by it in different countries speaks well for its having supplied a practical want. As is known, the quality of color in the blood is tested with this instrument by soaking a drop of blood into a piece of white absorbent paper, after



which the red spots thus obtained can be directly compared with a color scale of ten different tints.

The idea of using absorbent paper for estimating the color of the blood, I found first in Ehrlich and Lazarus,[1] and it was a development of this idea that led to the construction of the hemoglobinscale.

Since this simple apparatus has come into the market in book form it has repeatedly been subjected to control examinations. Among others, Hedemies[2] finds that the exactness of the results obtained by the scale do not fall far short of those as determined by the Fleischl hemometer, and are fully equal to those given by the Gowers method. Aspelin[3] in his hematocrit examinations, has likewise found in the main a good correspondence with the Fleischl-Miescher hemometer, after which the scale has been constructed.

It has been demonstrated that the hemoglobin scale, in addition to the practitioner's needs, can also be of service for clinical and other purposes. Cabot says ("Clinical Examination of the Blood") that it "can be used by any one with sufficient accuracy for practical purposes, and with a celerity that makes hemoglobin estimation no more of an undertaking than feeling the pulse," and that "it deserves to supplant all other hemoglobinometers in clinical work" and also "I have used the instrument in several hundred cases, and have never yet been misled by it." Of course this, like all other hemometrical methods, requires a certain amount of practice in order that the results obtained shall be entirely reliable.

The above holds good, however, only on the hypothesis that the colors in the scale which is used are exact, and the difficulties have not been slight in the obtaining of a thoroughly correct reproduction, as not only of the intensity, but also of the shades of change from color to color. There is also added the difficulty that the printed colors undergo a change unless every precaution against the same is used, and it is on this account that I find myself called upon to personally superintend the preparation of the scale.

A piece of white absorbent paper of suitable quality is, therefore, a great asistance to a practitioner in making an anemia diagnosis and for judging its intensity. Ehrlich and Lazarus[4] express themselves on the subject in the following manner: "If this easy, convenient method, which can be used even during a consultation hour, were to be followed more frequently, it would make the popular diagnosis, 'anemia,' lose ground. In the case of neurasthenic patients, who only too often believe themselves to be anemic, and who look anemic, a *demonstratio ad-oculos* is often sufficient to convince them to the contrary."

In addititon to this, the piece of absorbent paper gives us, in different cases, a number of other valuable suggestions. With the publication of my color scale[5] I have drawn attention to a phenomenon which at times may be noticed in anemias in the spot of blood on the absorbent paper. Around the colored spot extends a moist ring, which is especially visible when the paper is turned toward the light. The ring always denotes a great decimation of the number of blood corpuscles, and it has been shown that, as a rule, this condition first appears when the number of blood corpuscles per cubic entity is reduced to about half the normal, or less. The greater the diminution the broader is the moist transparent ring. The presence of the ring is thus an indication that a graver anemia exists. This phenomenon, as a rule, does not appear in chlorosis, even of considerable intensity, in which, in general, the diminution of blood corpuscles does not reach an excessive degree. On the contrary, it is seldom absent in pronounced so-called pernicious anemia. These observations have since been confirmed from other quarters.

Finally there is still another form of disease of the blood which, in a special manner, makes its presence known by the absorbent paper test. I refer to leucemia. If the diagnosis has not already been made the attention cannot fail to be immediately directed to the condition as soon as the attempt is made to drop blood on the paper. In striking contrast to the usual conditions we find that the drop is sucked up by the absorbent paper very slowly, thus an appreciable time elapses before the spot has dried sufficiently to allow the test to be made. With a closer scrutiny it is perceived that the shade does not accord with any of those found in the scale, for which reason also an estimate of the strength of the color cannot be made. The large number of leucocytes, it is true, must be considered to be responsible for the change, in the physical condition of the blood. Only a great augmentation of the amount of white blood corpuscles, such as we find in leucemias, is shown in the above-named manner by the absorbent paper. Possibly the altered condition of the leucocytes themselves plays a part herein.

As a valuable addition to our usual simple physical examination methods the absorbent paper test for the blood is, therefore, under many circumstances not to be despised by the practising physician.

THE CLIMATE AND WATERS OF HOT SPRINGS, VIRGINIA.

BY GUY HINSDALE, A.M., M.D.,
OF HOT SPRINGS, VA.

THE Hot Springs of Virginia owe their popularity as a health resort to a remarkable combination of climate, a variety of mineral springs for external and internal use, a complete bathing equipment, and an establishment which provides accommodations of the first rank. Although a large proportion of visitors come for the treatment of various affections, there is much to attract the ordinary tourist.

The climate is distinctly stimulant, as might be expected from an altitude of nearly 2,400 feet in a valley among the mountains of Southwestern Virginia. Compared with New York, Boston, Philadelphia or Chicago, the air is rarer, dryer, purer, and more invigorating. The cold in winter is not so penetrating, and the summer heat never so intense.

Annual Summary.

HOT SPRINGS, BATH CO., VA. Elevation 2,400 feet.

1899.

Annual mean temperature,		51.7° F.
August 4, highest,	91°	
February 10, lowest	14°	
Total precipitation for the year,		40.77 inches
June, greatest monthly precipitation,		7.60 inches
November, least monthly precipitation,		0.61 inches
Total snowfall,		4 inches
Number of rainy days,		65
Number of clear days,		222

1903.

Annual mean temperature,		49.4° F.
August 25, maximum	88°	
February 18, minimum	—6°	
Total precipitation,		47.66 inches
June, greatest monthly precipitation,		7.78 inches
May, least monthly precipitation,		1.25 inches
Total snowfall,		19 inches
Number of rainy days,		112
Number of clear days,		177

October, November and December are the months of least precipitation; June and July are characterized by heavy thunderstorms. The average annual rainfall is 40 inches.

In 1903 the last killing frost was April 27, and the first October 18.

The temperature at Hot Springs during the past winter, which was unusually severe, reached —6° F. The highest recorded was 98° F. There

The Bath House, Virginia Hot Springs.

is a wide diurnal variation, and the summer nights are cool, and the mid-day temperatures in winter are often 30° F. above the minimum at night.

The air is much dryer than at the seaboard. The soil is mixed with clay in the valleys, and the outcropping of the Shenandoah limestone accounts for the calcareous nature of the water. But close to the limestone are formations of trap and shale. The outcroppings of trap are vertical and form the backbone of the ridges so common in this portion of Virginia. The shale affords a purer and more palatable water, and it is this which affords the ordinary water for table use. The geological formation is a glacial drift, and most beautiful erosion effects are seen all through the valley. Great masses of limestone, gravel, and detritus are massed along the hillsides, and some remarkable effects have been produced. Water courses penetrate the soil for miles under-

ground and emerge in bold streams from under the ridges, which rise a thousand feet above them.

One of the striking features of the locality are warm springs and cold springs in very close proximity. These may vary 45° F. within fifteen feet of each other, and evidently, have their origin in widely different sources.

The mineral springs owe their efficiency mainly to the methods employed in their application. The Boiler Spring, which is used for bathing, has a natural temperature, when delivered in the baths of 104° F. It contains total solids of 34 grains per gallon, mainly calcium and magnesium carbonate and magnesium sulphate. Its contained gas, CO_2, amounts to twenty-four inches per gallon. The flow from this spring is about 130,000 gallons daily. This water is conveyed by gravity in protected iron pipes, 200 yards to the bath-house, where it is used for the spout and tub baths. The pressure of the spout bath may be regulated up to a maximum of eighteen pounds to the square inch, and for the tub bath may be moderated with colder water. Cold water for douches can be had in every bath-room. The tubs are constructed so as to afford a strong, buoyant flow of water freely flowing over the sides and drained away. Connected with the twenty-six bath-rooms are rooms with couches for hot packs, for massage, and a solarium for rest afterward.

In addition, there is the latest and most complete hydrotherapeutic apparatus, the Baruch-Richter douche table, with circular, rain and Scotch, jet and perineal douches and hot-air cabinets. Trained masseurs and attendants are employed. The physicians thus have at their command the very best combination of means for the successful treatment of gout, rheumatism, and many nervous diseases, including insomnia, neurasthenia, hysteria, hypochondria and malnutrition.

There are walks of moderate and regular grade, with resting places every tenth of a mile, and mountain paths which are available for graded exercises and the reduction of overfatness. The climate and attractive scenery add much to the value of this resort.

The property of the Hot Springs Company embraces several thousand acres, and its natural beauties have been conserved by most intelligent engineering. The hotel, which accommodates over 600 guests, occupies an elevated knoll near the principal springs. It is a substantial brick building in the colonial style, and was built three years ago on the site of a former structure. Its reputation is of the highest order. While in no strict sense a sanatorium, it provides many of the features which invalids and others desiring medical treatment require. These include a diet menu,

with unlimited milk served in sealed bottles from a dairy where the herd of Alderneys is inspected and tested at proper intervals; an ice plant in connection with the hotel, and a supervision of the springs and general water supply and sanitary arrangement by a competent chemist and hygienic expert, Dr. Henry Froehling, of Richmond. For the convenience of bathers the hotel is connected with the bath-house by an enclosed passage-way.

The waters are applied by attendants in accordance with prescriptions. These indicate the use of the spout, from a fixed nozzle delivering warm water, 104° F., at a pressure of sixteen to eighteen pounds to the square inch; a tub bath at various temperatures from 95° to 104° F. for not over five to ten minutes, followed with a pack in three or four hot blankets, a cold douche and an alcohol rub. The attendants may also rub the patients in the tub. Usually not all these features are employed in the same bath.

Analysis of Healing Spring Water.[1]

	Grains per gallon.
Magnesium carbonate,	3.435
Magnesium sulphate,	6.076
Calcium sulphate,	2.380
Calcium carbonate,	23.065
Sodium sulphate,	1.673
Sodium chloride,	0.143
Potassium sulphate,	2.586
Potassium chloride,	0.183
Lithia carbonate,	0.0356
Ferrous carbonate,	0.193
Alumina,	0.048
Silica,	2.677

The Healing Springs, which are three miles distant, are owned by the Virginia Hot Springs Company, which also controls the Warm Spring, seven miles farther up the valley. The Healing Springs water is the most efficacious and most generally used for internal administration at this resort. It contains 36 grains of total solids per gallon, principally calcium corbonate, magnesium sulphate and carbonate of sodium sulphate. It is considered, by reason of its diuretic properties and its acceptability to the stomach, the best water to eliminate uric acid from the system. Unlike the sulphur water, it keeps well after transportation, and is suitable not only for use during a residence at the spring, but for the "after-treatment" at home. The magnesia, sulphur, and soda springs are also used as individual cases require. The temperatures are 98.2°, 99.4° and 74° F., respectively.

It is a common observation that a decided reaction follows the first three or four baths. This should be anticipated, and is in no sense an indication that the baths do not agree with the patient. This febrile reaction, with swellings of the affected joints, is the first step toward the elimination of morbid products.

It is not claimed that the marvelous results from bathing in these hot springs are due to absorption by the skin of the mineral constituents of the water, but they are attributable rather to a temperature effect. The heat or cold stimulates the peripheral nerves of the skin, and these, in turn, favorably affect the central nervous system.

It is a well-established fact, not, perhaps, generally recognized, that water holding less saline matter in solution is more readily taken up into the blood stream than water containing much saline matter. The denser waters are liable to cause a sense of pressure and fulness of the stomach. The waters used at the Hot Springs of Virginia are of the lighter class, none of them containing over 35 grains of solid contents per gallon. The waters are therefore easily borne. The only objection is that in susceptible persons there may be slight constipation during their use.

Out-of-door sports are a great help in treating patients at the mountain spas. Exercises on the golf links, on horseback, and mountain climbing all have their place in treatment, and, properly used, make life attractive. On the other hand, there is a great tendency at a fashionable resort to indulge in rich foods and to drink wines and strong liquors. These tend to undo the good effects produced by the baths and the climate. Too much stress cannot be placed on the proper regulation of diet and on abstinence from alcoholic drinks in the successful treatment of gout, rheumatism, and most nervous affections. Many visit the Hot Springs of Virginia and similar resorts to restore a proper function to the stomach, the kidneys, or the liver. The use of hot baths and diuretic waters accomplishes much; as a rule, it is easier to break off bad habits at the springs than it is at home, and under new medical authority much can be done for these cases.

1 By Dickore and Morgan, Cincinnati.

THREE CASES OF PROBABLE PSITTACOSIS.

BY HERMAN F. VICKERY, M.D.,
OF BOSTON;
WITH BACTERIOLOGICAL REPORT
BY OSCAR RICHARDSON, M.D.,
OF BOSTON.

In 1879 J. Ritter[1] reported a house epidemic of severe pneumonia which he ascribed to contagion from parrots, or rather the cages in which the birds had been transported. Similar observations were made by Ost[2] in Berne in 1882, and Wagner[3] in Leipzig in 1882 and 1886.

In December, 1891, 500 parrots were purchased in Buenos Ayres for the Paris market. Of these 300 died on the voyage and 200 reached Paris in February, 1892. During that year there were 49 cases of the disease now known as psittacosis, ascribed to infection from these parrots, with 16 deaths. In 1893, seven cases with five deaths; in 1894, two cases, both of which recovered; in 1895-96, 12 cases, with three deaths.

In 1894-95 there were house epidemics in Florence and Ponto of a malignant atypical pneumonia, appearing almost simultaneously in several members of the same family, or even involving the whole family, and in some instances conveyed directly from one individual to another.

This visitation was ascribed to parrots which had been imported by way of Genoa from South America. Observations[4] were made by Banti, Malenchini, and Palamidessi.[5]

In 1897 it was reported[6] that in Genoa 14 persons fell sick and eight died because of two parrots brought from Brazil.

In 1898 in the Julian Venetia three inmates of one house fell sick and of these two died where two parrots had died shortly before. Leichtenstern[4] observed house epidemics in Cologne in 1898. In one there were ten cases and four deaths; in a second eight cases with one death. Leichtenstern regards it as probable, but not susceptible of absolute proof, that both of these cholera, but more like Nocard's bacillus, though apparently not identical with it.

In 1896 Gilbert and Fournier[10] reported five cases of psittacosis in man; of these two died. In the heart's blood of one Nocard's bacillus was found post mortem. It proved to be an extremely virulent organism, killing rabbits, mice and pigeons within fourteen to eighteen hours after inoculation.

Nicolle[11] reported, in 1899, an epidemic affecting eight persons, of whom four died. Although he did not find Nocard's bacillus, he obtained a serum agglutination from a culture of that bacillus in dilutions of 1 to 50 and 1 to 60. The serum also caused a clumping of typhoid bacilli,

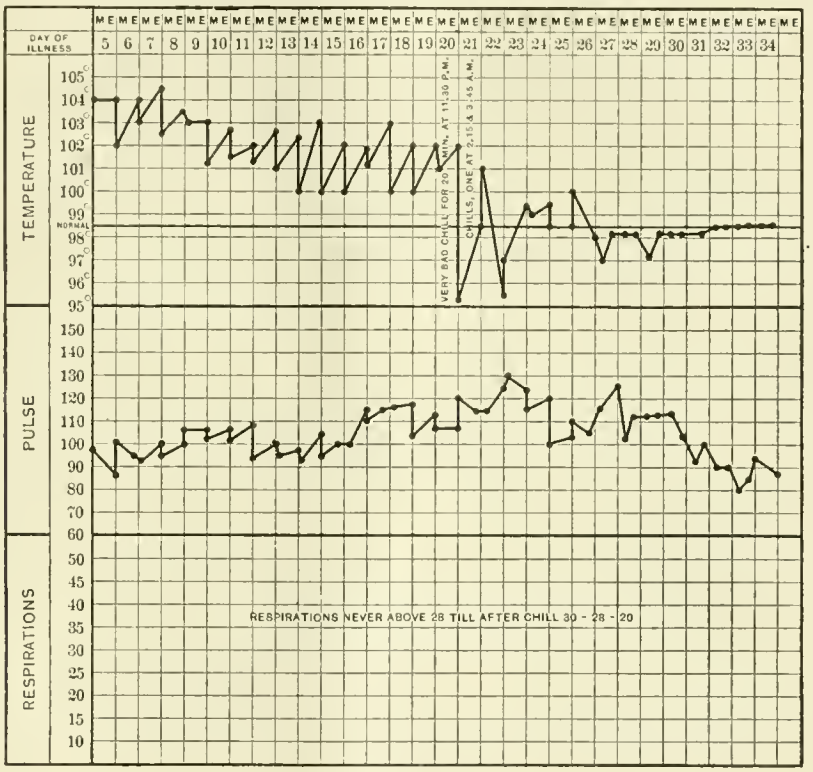

Chart of Mr. M.

groups of cases were referable to contagion from parrots.

In 1880 Eberth[4] reported the discovery of enormous numbers of micrococci in the body of a gray parrot, and in 1883 M. Wolff[8] examined the bodies of 12 gray parrots from the Guinea coast with a view to explaining the immense mortality in parrots brought thence to Germany. He also found micrococci in great numbers.

In 1893 Nocard[9] isolated a specific bacillus belonging to the group of colon bacilli.

Among the Florentine cases Palamidessi (already mentioned), in a house epidemic which attacked five persons in one family a few days after a South American parrot was introduced, found a microbe similar to the bacillus of chicken

although the patient had never suffered from typhoid fever; but Widal[12] and Sicard[4]—1896—claimed that they could differentiate the typhoid bacillus from Nocard's by the serum reaction.

The symptoms of the disease in parrots are: loss of appetite, debility, drooping of the wings, and diarrhea, ending with convulsions and death. In man the symptoms of the Paris epidemic might be summarized as those of a grave typhoidal condition, with atypic pneumonia. The onset is acute, often with chilliness or a true rigor. Exceptionally the disease begins insidiously, but in that case there is apt to be a chill when the pneumonia begins. The temperature is often 103° F. on the first day and perhaps 104° F. on the second day of the illness. The

fever is more or less continuous, with a termination by lysis. In many cases successive foci of pneumonia develop, giving the temperature curve a recurrent type.

With the onset the patient is feeble and depressed; he usually has a violent headache and is often dizzy. There may be delirium. As a rule there is obstinate constipation, but some cases suffer from diarrhea. The spleen is always enlarged; there may be a roseolar eruption or petechiæ. From the beginning of the disease there is a noticeable cough, and on auscultation subcrepitant râles are found throughout both lungs; then after a few days there is a slow development of pneumonia, which may be either lobular or lobar. In some cases, however, there may be no evidence of consolidation.

In the cases reported by Leichtenstern, above referred to, the illness was similar. There was the great weakness and depression from the start and almost invariably a severe headache, but no cases had delirium. As a rule, there were no abdominal symptoms. The spleen was not found to be enlarged in any of the cases, thus contrasting with the Paris epidemic.

The period of incubation varied from one to three weeks in the Paris and Cologne epidemics. Warthin states that it is from seven to twelve days. The mortality is put at 37 per cent. The disease is said to be more severe in the elderly. Treatment is purely sympathetic.

Czaplewski made bacteriological investigations in Leichtenstern's cases. He sums up as follows: First, the parrot which he examined did not die of infection from Nocard's bacillus. Second, no conceivable etiological connection can be proved between the disease of the parrot and the illness of those in whose house it was. He adds that he does not at all wish to deny the possibility of the existence of a genuine infectious disease in parrots communicable to man.

As Warthin states, "the bacteriology of psittacosis and the true relations of the parrot disease to the atypical pneumonia seen in man are yet to be definitely determined."

This outline of our knowledge as to psittacosis may be convenient for comparison with three

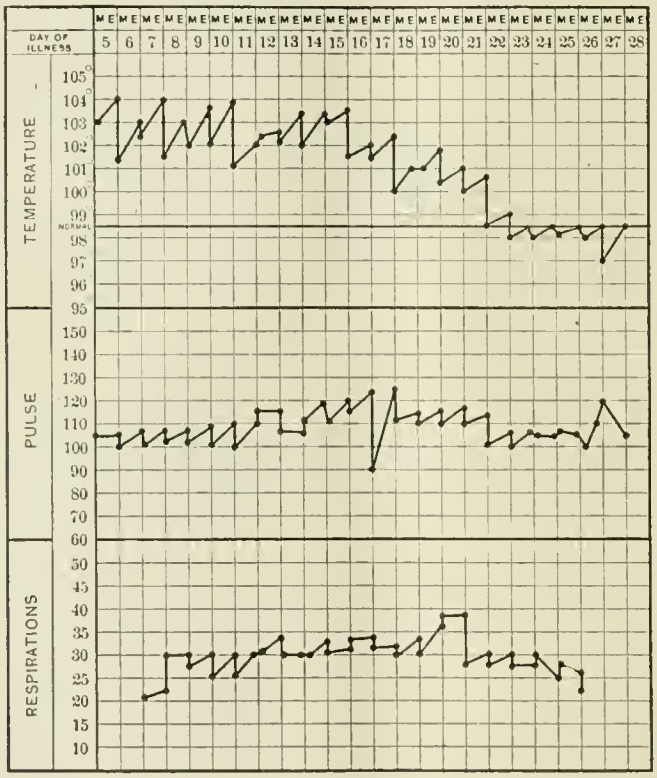

Chart of Mrs. M.

cases of disease which came somewhat under my own observation in Wolfboro, Carroll County, New Hampshire, in December, 1903. They were the patients of Dr. Nathaniel H. Scott, and were seen by me in consultation with him and Dr. Stillman P. Getchell, both of Wolfboro. No similar cases preceded or followed those about to be reported, which affected three out of four members of one household.

Mr. and Mrs. M. visited New York City in November, 1903, and while there they sent home to Wolfboro a green parrot, which arrived November 7. They returned one week later. The parrot had a bloody diarrhea and died November 21. It was kept in the sitting room occupied by Mr. and Mrs. M., and was cared for especially by their domestic, Mrs. J., and somewhat by

Mrs. M. The fourth member of the household was Mr. J., the husband of the domestic; but Mr. J.'s work kept him throughout the day away from home, while the head of the house, Mr. M., spent much time in the room where the parrot was.

Case I.—Mrs. J., a young woman of previous good health, was taken ill suddenly November 25, eighteen days after the parrot arrived and four days after it died, with prostration, pain in the right scapula, a temperature of from 102° to 103° F., vomiting and constipation. The temperature was about 103° F. for a week, then was normal three or four days, and rose again, remaining elevated for a week, and finally terminating by lysis, with the slow recovery of the patient. There was no cough.

Case II.—Mr. M., aged sixty-two years, once had a severe attack of typhoid. His habits and general health were good, but eight years ago he suffered severely from prostatic trouble, complicated by an abscessin the scrotum, which caused destruction of both testicles and was followed by apparent atrophy of the prostate gland, with considerable relief of the bladder symptoms. For some days previous to his present illness he had seemed languid. On November 29 he was obliged to go to bed with a temperature of between 103° and 104° F. and a pulse of about 100. He was first seen by me December 11, when his temperature was 103° F. in the afternoon, with a pulse of 104 and a condition, according to Dr. Scott, much more favorable than some days before. The leucocyte count was 8,640. The tongue was rather dry but clean. The respirations were about 28 per minute, and there were no marked pulmonary symptoms. The walls of the radial arteries seemed calcified, and the aortic second sound was accented. When seen by me again on December 16 the white count was 5,780. There were moist râles in both bases, especially posteriorly, with slight dulness and diminished respiration in the lower part of the axilla and back, on the right side; but no bronchial respiration could be detected. The throat contained a thick, viscid, and almost membranous secretion. He had been rather worse since December 11. He was somnolent and had Cheyne-Stokes respiration. On December 23 he was again seen by me and seemed to be slowly improving, but on the seventeenth he had a severe chill with great prostration, and on the eighteenth two similar attacks. These, however, seemed to be referable to cystitis, with offensive, purulent urine, which improved upon the administration of urotropin, with gradual and permanent convalescence.

Case III.—Mrs. M., aged sixty-seven years, had a family history of apoplexy and diabetes. The patient had been ageing rapidly in the last two years. She fell ill November 27, and was seen by me December 11. There was high fever and delirium, with constipation. The leucocyte count was 13,200. The pulse was 120 per minute, and Dr. Scott stated that it had been growing progressively weak and rapid. The chest was full of moist râles, which in some places seemed high-pitched, but no distinct consolidation could be made out. The abdomen was soft; no enlargement of spleen or liver could be detected, either in her case or that of her husband. Within a day or two her condition became still worse, but it was improved by a purge, and by the injection of normal saline solution with adrenalin. On December 16 the white cells numbered 8,960. There was a white deposit in the mouth and throat which proved to be thrush. While moist râles could still be heard in both lungs, they were fewer than five days previously, and now coarse dry râles were audible. The heart was stronger. From this time she improved quite rapidly. On December 11 and December 16 the Widal test proved absolutely negative in both Case II and Case III. On December 16 paratyphoid and paracolon tests were likewise negative.

The general aspect of the case should be mentioned. It was well described by Dr. Scott and Dr. Getchell, when I first had the honor of meeting them, as being more like typhoid than anything with which they were familiar, but yet probably not typhoid fever. Temperaure charts of both Mr. and Mrs. M. accompany this report. No eruptions developed in either case.

With regard to the etiology. As has been said, no similar cases existed in the village. The sanitary condition of the house had been brought into question. It occupied an elevated and healthful location, but the plumbing was defective. The pipe leading from the kitchen sink to the cesspool, into which all the waste material of the house was drained, had no trap, and furthermore, it did not reach to the surface of the water in the cesspool, so that there was a free access of the air from the cesspool into the kitchen; but there had been no change in the plumbing for three years, and for months a peculiar smell had been noticed occasionally in the kitchen.

Conditions such as these are highly undesirable, and they do promote illness by depressing the general condition of the occupants of the house and rendering them vulnerable to specific infectious agents, but it seems unlikely that they can account for so explosive an outbreak in persons who for several years were accustomed to them.

If Mr. and Mrs. M. brought some infection with them from New York, it is difficult to explain why the domestic fell ill before they did. Moreover, influenza, the likeliest disease to be considered, has usually an incubation period of two or three days, while they returned eleven days before the first illness occurred.

The advent and demise of the parrot were not known to me until my second visit, December 16. I then invited the cooperation of my friend, Dr. Oscar Richardson, assistant in the Clinicopathological Department of the Massachusetts General Hospital, and his report is as follows:

Bacteriological Report.

At the request of Dr. Vickery, I made, in December, 1903, examinations of blood taken from the cases which are described in his paper.

The blood examined came from Mr. J. H. M. and Mrs. J. H. M., and was subjected to the following agglutination tests. The blood from each case was added to the bouillon cultures, twenty-four hours old, of a known typhoid bacillus and a known paratyphoid bacillus, in the proportions of one of blood to ten of culture, and observed for half an hour. On the expiration of the time of observation, all the tests were found to be negative, so that higher dilutions were not made.

A short time later more blood from each case was obtained and further tests made with different strains of typhoid bacilli and bacilli of the paratyphoid-colon group, but all the tests were negative.

Finally an agglutination test was made with a bouillon culture of streptococcus-like micro-organisms recovered from the spleen of the parrot associated with the cases under consideration, but this test, like the others, gave no evidence of any reaction.

Stained cover-glasses of the blood were also made and examined, but no malarial organisms were found, and the blood showed nothing worthy of note, except for a slight increase in the number of leucocytes. Cultures were made from the throats of these cases, but the growths obtained showed nothing unusual.

At the time when the cases under consideration were taken ill they had in their household a sick parrot, which finally died and was buried. As soon as this fact was learned by Dr. Vickery the parrot was exhumed, packed in a box and sent to the laboratory, where it was received on December 21, 1903. The bird had been buried for about a month.

At the autopsy, which was held immediately, the body of the bird gave forth no marked odor and outwardly showed nothing worthy of note. On section the viscera presented no demonstrable lesions, and the post mortem changes, which were well marked in the intestines, were not apparently so far advanced in the solid organs. The brain was not remarkable.

Cover-glasses were made from the heart blood, liver, spleen, and the marrow of the wing bones and stained with Löffler's blue and Wright's blood stain, but on examination no bacteria or other micro-organisms were found.

Aerobic and anaerobic cultures were made on blood serum from the following sources: Heart blood, liver, spleen, the marrow of the wing bones, and the brain. After forty-eight hours in the incubator at 37° C., the cultures showed no visible growth, with the exception of the aerobic culture from the spleen. This culture showed on the surface of the medium, one small, round, gray-white colony, and its water of condensation had a slightly cloudy appearance.

Microscopical examination of the cultures showed that no bacteria were present in any of them except in the aerobic culture from the spleen. The single colony in this culture was found to be a micrococcus morphologically and culturally like the streptococcus. The water of condensation of the culture from the spleen was found to contain a similar organism to that in the colony.

A guinea-pig was inoculated from a twenty-four-hour-old subculture in bouillon from the colony, but the animal remained unaffected after many days.

This streptococcus-like micro-organism found in the culture from the spleen is, therefore, regarded as having no etiological relation with the unknown cause of death of the parrot, and it is probably a contamination.

It is to be regretted that an examination of the parrot could not have been made about the time of its death, as it seems quite probable that by cultures and cover-glasses made then, any bacterium that might have been the cause of the possible infection of the bird would have been discovered.

These negative results of the various tests and examinations recorded above are disappointing, but they are of considerable importance in ruling out those diseases the atypic forms of which psittacosis resembles. [Here ends Dr. Richardson's report.]

To sum up, three occupants of one house are taken ill almost simultaneously and two nearly die of a disease corresponding fairly well to the descriptions of psittacosis, and not easily placed in any other category. The time elapsing after the arrival of the suspected parrot corresponds to the period of incubation in psittacosis. The milder attack of the young patient is according to the rule. The only member of the household who escaped illness has had little to do with the parrot, but is the husband of one of the patients, Mrs. J. H. M.

A personal visit to the dealer in New York from whom the parrot was purchased had no satisfactory result. In another shop which obtains its parrots from the same wholesale house, I learned that three employees had been ill this spring, two with pneumonia and one with an attack of grip.

THE DISTRICT NURSE IN HER RELATION TO CASES OF PULMONARY DISEASE.[1]

BY ARTHUR WILLARD FAIRBANKS, M.D.,
OF BOSTON, MASS.

Excepting the contagious eruptive diseases there is perhaps no class of disease with which you come more often in contact, in your district work, than the various affections of the lungs. A few remarks on these conditions, and the relation of the hygiene of the home to their treatment and prognosis may not be without interest to you in your work.

In perhaps no other form of illness is your opportunity for the accomplishment of much and lasting good greater than in cases of pulmonary disease. Nowhere in the domain of medicine today is the fight against ignorance and superstition as great as it is against the beliefs in regard to the class of cases of which we are speaking. Your share in this contest is a great and important one. By unremitting effort it is in your power not only by your work to greatly aid the physician in his attempt to relieve his patient, but also to prevent the occurrence of many a similar case of illness.

Let us first consider the single matter of *ventilation*. While a proper supply of fresh air, in other words oxygen, is a necessity for the well, if they are to remain well, it is all the greater necessity to the sick, if they are to recover their health. But it is obvious to you that in no form of illness is an adequate supply of oxygen so requisite as in pulmonary disease; and in no class of cases is the popular fear of fresh air so great as in these very cases. Here is therefore where the battle must be fought, and, by regulation and constant supervision of this factor alone, from the standpoint of both cure and prevention, your opportunity for good deeds is boundless.

In the majority of other affections we can do without the function of the organ affected for a greater or lesser length of time, in part at least. We may even take deliberate measures to restrict its action for the sake of the benefit derived from the rest so obtained. Even in the case of the heart, when it is diseased, we can to a certain extent quiet its action, so as to afford it relative rest. But through the lungs must constantly flow, day and night, in consciousness and in sleep, that vital current necessary to all animal life, that element essential to the welfare of every portion of the body.

Consequently, whatever the condition of the individual in whole or in part, the lungs must continue, without intermission, to perform their duty or death results. When, however, the organ itself is diseased it is obvious that its function must be more or less impaired. Important then as is a full supply of oxygen to the lungs in health; how much greater is that necessity when their function is impaired by disease. Since we cannot stop their action and give them rest while they are recovering, and since we know that, crippled as they are, they cannot fully meet the demands of the body for oxygen, we must favor them all we can by furnishing them with as free and abundant supply of oxygen as possible, that they may answer this demand with a minimum expenditure of effort. The greater the involvement of the lungs by the disease, the greater naturally is the impairment of their function, and thus it happens often that the *best* we can supply of Nature's air does not contain sufficient oxygen to compensate for the diminished ability of the lungs to absorb it, and we are then informed by the increasing dyspnea and deepening cyanosis that we must furnish it in more concentrated form, or death will ensue.

We then, as you know, have recourse to the inhalation of pure oxygen.

Perhaps I cannot better illustrate the subject than by mentioning a case typical of those which you see in the work you are doing. A few weeks ago I was called to see a boy of about twelve years, who had been taken suddenly ill the previous night. I found the patient dull and disinclined to speak, except to complain of occasional sharp pain in the side, with high fever, labored breathing and moderate cyanosis. Examination proved it to be a case of lobar pneumonia. The room was small and perfectly dark, although there was bright sunlight outside. The one window was tightly closed, with blinds shut and curtains down. The single door opened into the kitchen in which there was a hot fire, and some clothes drying on a line, while on top of the stove was a frying-pan in full operation. The two windows of this kitchen opened on a narrow passageway. The atmosphere of this room may be imagined. When told what the illness was the mother remarked that she knew it was pneumonia "by the way he breathed." Yet here was her boy struggling for air, for the very element that her maternal solicitude impelled her to so carefully exclude. Solicitude it certainly was, for she made not the slightest objection, when the situation was explained to her, the bed turned, and the window opened liberally at the top, and to her faithful care in the following days the boy owed his life.

Apart from enabling the diseased lungs to do their work with as much facility as we can afford them, we also know that a blood well supplied with oxygen is furnished with effective ammunition in its war against the disease germs. This is an additional reason for pure air in pulmonary as well as other diseases. Then not the least consideration is the comfort afforded the sufferer. Sometimes the proper ventilation of a close stifling sick-room reacts on the feverish patient somewhat as does a light sponge bath in the case of a feverish restless child. Refreshing peace and sleep takes the place of fretfulness and unrest.

The subject of fresh air, however, brings us to a consideration to which we must come, sooner

[1] Lecture delivered to the nurses of the Instructive District Nursing Association, Boston, April 28, 1904.

or later, in everything we do in life. This is the subject of *moderation*. We must temper our acts with judgment in this as in all things. We must consider the case, our patient before all else. We must not fear to supply Nature's tonic in full dose when sure that it will be well borne. On the other hand we should not hesitate to protect our patient if our judgment warns us of harm. I cannot but feel that we have sometimes gone too far in our enthusiasm for fresh air and have occasionally forgotten that fresh air is not necessarily *cold* air. I think the pendulum of enthusiasm will swing back in time until it occupies a point not quite midway, but a little to the side of the present view, for it is certainly better to err on the side of too much fresh air than to sin in the other direction. I urge you strongly however, of the necessity of some care in the exposure of young children to too cool air. The younger the child the greater the need of caution. We must remember the sensitiveness of the mucous membranes at this period of life and especially in a class of cases of which I will speak later. The common fear of fresh air is really a fear of cold air and arises from the frequency with which disease is attributed to "taking cold." It is well to explain to the layman that the "taking cold" undoubtedly does diminish our resistance, and renders one more likely to contract certain diseases, such as pneumonia if we are exposed to it, but the disease once started is not made worse but materially better by the breathing of fresh moderately cool air.

The Temperature of the Sick-Room in Pulmonary Affections.—This is also a matter largely coming under your supervision and one of considerable importance to the welfare of the patient. In general it may be said that the temperature most suitable for other cases of illness is also that indicated for pulmonary affections. We shall find some variation necessary according to the nature of the case. An average of perhaps 65° F. is best, somewhat lower where there is high fever, sometimes a little higher in certain cases, as we shall see later. This matter of the temperature is closely associated with the degree of dryness of the atmosphere, a very important consideration in affections of the lungs, which we will notice more minutely in a moment. It should be borne in mind that in those cases where we desire the air to be moist and employ means to that end, the temperature of the room should be kept *considerably* higher than the above average.

Other things being equal, an atmosphere of higher temperature is capable of holding more moisture in suspension. In cases requiring a dry atmosphere we may have it warm or cool according to the means we employ to produce the dryness. We shall also see that the temperature most suitable for our pulmonary patient is materially modified by his age, by his state of vitality, and by the disease from which he is suffering. The young and the aged are much more sensitive to cold air and especially to a *sudden reduction* in temperature than are the middle-aged. They not only acquire affections of the lungs and bronchi under these circumstances, but, when already afflicted, are much more likely to be made worse, or to suffer a relapse when convalescent. In these cases when for some special reason it is necessary to cool the sick-room, it should be done gently and gradually. *Evenness* of temperature in these cases is a desideratum. Into this same class must be placed also those of our ordinary patients whose vitality is reduced by disease. They become for the time being, amenable to the rule for the extremes of life.

Another important consideration ordinarily overlooked, I think, is the life to which our patient is accustomed. We should consider whether he has been accustomed to an active out of door life or whether he lives most of his time in overheated, poorly ventilated rooms. In the former instance his resistance to, in fact his need of cool stimulating air may be great. In the latter case, while his need may be equally great, his capacity of receiving the same is infinitely less. So here again the question of *rule, tempered with good judgment,* plays its part. There is a fact of much importance in connection with the temperature of the room, especially in affections of the lungs in children.

In the average room, even in well-built houses of the better class, the temperature *near the floor is considerable lower* than it is higher up in the room. This is all the more likely to be the case in the dwellings of the poor. Thus the little one sitting on the floor, or in a low chair, or when running about, is exposed to a different temperature than that of which you are cognizant judging from your feeling or from the reading of the thermometer higher up on the wall of the room. Not only is the air cooler in the lower strata of the room, but it is almost invariably in *motion*. The more windows and doors there are the more marked are the currents of air sweeping along the floor. In a sensitive child suffering from acute or subacute bronchial affections this fact becomes of prime importance. Many such children are not confined in bed but are up and about the room. In the middle of the forenoon or afternoon, the child becomes sleepy and is laid on the bed. As soon as the child falls asleep the mother is overpowered by the fear that he will "catch more cold" and usually covers him warmly. After an hour or two he awakes, often in a state of perspiration, and wishes to get up. The mother takes him up, and, busied with her work, puts him on the floor to play. With warm and relaxed skin he is immediately subjected to the cooler air and the drafts along the floor. He "gets more cold," the inflamed condition of the bronchi is still further perpetuated and days of gain are lost. A well child in this way often acquires a bronchitis, while the mother wonders how it happened when she covered her little one so solicitously while it was sleeping. I am con-

vinced that many colds and lung troubles are contracted by children in this way.

In the case of the aged with enfeebled circulation in the lower limbs, this same difference in the temperature and movement of the air may be productive of harm. This is a very difficult matter to control. In the case of the aged, if, as is usually the case, they must sit most of the time quietly in a chair, much of the harm may be obviated by having them use a chair of rather more than the average height, and rest their feet and legs on a support of nearly similar height. When it becomes necessary for change of position to place the feet on the floor, a light shawl should be wrapped about the feet and legs. The best place for children is the bed if the affection is acute, or if a child during convalescence continues to have exacerbations of the affection.

The problem of perfect ventilation is far from solved even in the most modern homes.

I have already referred to the degree of *humidity* as a factor of importance in diseases of the lungs. This factor in the homes you visit varies even more than the temperature. In the one case your patient is subjected to the torrid and humid atmosphere of the family kitchen, surcharged with the steam from the wash-boiler, and tubs, or the cooking dinner. In another case, in a little room more remote from the constant heat of the kitchen, our poor sufferer lies or sits in an atmosphere completely deprived of the moisture it *normally* should contain, by an air-tight stove or a charcoal burner or similar contrivance, while occasionally in some favored family able to afford the luxury (?) you find the atmosphere made utterly irrespirable by a gas stove. All of this variation of cource irrespective of the type of disease from which our patient is suffering. You may judge the effect of the former state of affairs on a poor sufferer with bronchial tubes filled to overflowing with excessive secretion; while you will surmise that the atmosphere last described is not the one most soothing to our patient with his bronchi inflamed and swollen and dry, devoid of even the moisture they should normally possess.

In the case first described, if you cannot move the patient you had better have the tubes removed and the dinner cooked under the auspices of a charitable neighbor, if one can be found. That is, of course, if the family submit. If not, there is nothing you can do, except to pray that your patient may recover in spite of his friends. In the case that is being slowly dried fortunately the requirements of the situation are more easily met. Here you can take a tea-kettle, or any available receptacle, partially fill it with water and set it on the stove, thereby giving the thirsting bronchi welcome relief. Thus you see again there is a happy mean, in this as in other respects, which we should follow until we find that the particular character or stage of the disease demands more than the normal or less than the normal degree of moisture in the air the patient breathes. We shall find that sometimes it is necessary to surcharge the air with water vapor while in another instance we must subject the patient to a dry atmosphere. This is something the physician must direct, but until he does so it is for you to keep the air of the sick-room as near the normal as possible.

There is one other factor of the atmosphere of the greatest importance in lung affections, and this is its degree of *contamination by injurious gases and dust.* In all affections of the bronchi and lungs the very keynote of treatment is to remove all source of irritation from the air that, when breathed by the patient, must pass over the sensitive and inflamed mucous membrane. Yet in many of the homes into which you go the conditions are in the highest degree unfavorable to the attainment of this end. Not only do improper stoves fill the air with noxious gases, but ignorance in the use of even suitable apparatus is widely a source of injury, even among the supposedly more intelligent class. Then within a city's limits, with clouds of dust from the streets and the air filled with soft coal smoke, it becomes a matter of the greatest difficulty to shield our patient.

In the home itself, while often other forms of dirt are blissfully tolerated, a little dust resting for the time being at least harmlessly, is whisked into the air with a duster or a broom. No real thought of its *removal* is entertained. It is quite sufficient if it is sent into the atmosphere, to settle down after a time somewhere else, in a thinner, and consequently less visible, layer. Some of us I am sure have lived through the experience of seeing a chair, in anticipation of our occupation, hurriedly dusted off with a cloth infinitely more dusty than the chair, thereby sending our patient into an attack of coughing, to show us how much he was really capable of suffering without complaint. With dust teeming with bacteria, you may easily appreciate how a bronchitis of mild degree and with comparatively clean mucus secretion is converted into a severe purulent or even fetid form. There is also the danger of implanting in a lung whose vitality is impaired by the comparatively simple inflammation, disease germs of a much more serious form. Never permit a room to be dry swept or dusted while occupied by a pulmonary patient.

The *diet* in affections of the lungs should be, as for the well, the most nutritious obtainable, and of some variety, except in the presence of fever, when the rules as for any fever prevail. In such cases with the light liquid diet may be used the demulcent drinks mentioned later.

In acute cases, and especially in the later stages of convalescence and in subacute cases, the bronchial affection is but a part of a general depression in the function of the mucous membranes; and the stomach and intestinal tract suffer as well as the bronchi. Therefore in these cases there is frequent loss of appetite and inability to digest ordinary food.

Bathing.—If properly done and with certain precautions as to temperature of water and room, baths cannot be objected to, with the exception of very acute cases of bronchitis and in the aged or very feeble patient or where some exceptional feature of the case renders the amount of disturbance involved by the bath unwise, as for instance in cases with a tendency to pulmonary hemorrhage. After a bath, whether sponge or full bath, it is beneficial to warm the extremities by wraps if the patient is up, or by hot water bags if in bed. The temperature of the water used will depend somewhat on the particular features of the case, the age, the presence or absence of fever, etc. The temperature of the room in which the bath is taken should be comfortable, without drafts, and *especially not too warm.*

The mistake made by the layman is the taking of the bath in a close and overheated room. The effect under such circumstances is profuse perspiration and it is from this fact and not from the bath that he "takes more cold." Be especially careful in this respect where, as is occasionally the case in certain pulmonary cases, cold baths or cold sponging of the chest are ordered. It should be done in a *cool room*, the drying and the dressing accomplished as rapidly as possible, the clothes being slightly warmed. If you do not take precautions to have these rules observed, the very fact that he is to use cold water will induce the patient to take the bath in an overheated room and very probably he will take it as near the stove as possible. The effect of such a bath is *exactly the opposite* of that intended. The reaction of the cold water which, after the skin is dried, should consist of a warm dry glow, is followed on the contrary by a profuse perspiration so that the skin is moist and warm as the patient dresses, and this is succeeded by chilly sensations and cold extremities, and "more cold is taken" as he says.

Medicated baths are sometimes indicated in pulmonary affections of a chronic nature. The most useful perhaps and possibly the only one available among the class of patients with whom you are dealing is the salt bath. This is best made by using sea salt, obtained by the evaporation of sea water. It may be procured very cheaply. The bath may be a warm full bath, taken at night, or cool salt water sponging may be employed in the morning. The former is preferable I think. These baths are very useful adjuvants to the other methods of treatment in certain bronchial affections.

Massage is occasionally useful in certain affections of the lungs. It may be employed over the chest and accessory muscles of respiration to increase the power of expansion of the lungs. It may be used generally to assist the circulation or over the muscles of the extremities to diminish the impairment of muscular power incident to confinement and disuse. It is especially useful in conjunction with the baths in certain affections of which I will presently speak.

Inhalations, the superintendence of the administration of which usually comes within the province of the nurse, are used with great advantage in pulmonary disease. Steam impregnated with the vapor of creosote, turpentine, terebene and benzoin, oil of pine, eucalyptol, thymol, chloride of ammonium and iodine, is used. This is accomplished either by placing some of the substance in a vessel of water which is kept steaming or boiling over a stove or lamp, filling the atmosphere of the room with moist medicated vapor; or some may be placed in a pitcher or bowl of hot water and inhaled directly. In the latter case I have found a cone made of a newspaper and placed with the large end over the pitcher, and the small end over the patient's mouth, a very useful and practical expedient. Finally the medicated vapor may be obtained from a steam atomizer, where one can be afforded. Use the above mentioned substances in the following strength:

R Creosote ½ to 1 dram to the pint of water.
Carbolic acid ½ dram to the pint of water.
Camphor (spt. camph.) 1 dram to the pint of water (at 140).
Terebene ½ dram to the pint of water.
Turpentine.
Eucalyptol
Thymol
Benzoin (tr. comp.)
Oil of Pine.
} ½ dram to the pint of water.

If to the latter substances, after they are placed in the water, is added, a dram of light carbonate of magnesia, the diffusion will be aided.

The chloride of ammonium may be used dry by heating a little in a spoon over a lamp. The camphor and the terebene are best used in the pitcher or bowl by direct inhalation.

The inhalation of oxygen will be mentioned in connection with pneumonia.

Counter-Irritation over the chest is sometimes very useful in affections of the lungs. It takes the form of stimulating liniments or poultices. These contain slightly irritant substances that dilate the small blood-vessels of the skin and probably stimulate reflex nervous action; in these ways influencing the circulation and the capacity of the smaller bronchi and air cells. Heat, it should be remembered, acts in this way. The liniments usually contain ammonia, camphor, turpentine, capsicum, cinnamon or similar substances. The poultice may be made of flaxseed or wheat flour mixed with mustard or other spice. Some care to avoid blistering is requisite, especially in the case of children. If the flaxseed poultice is large, mustard may be added to the amount of one or two tablespoonfuls, in which strength, unless the skin is very sensitive, it may be left on some hours.

A good poultice for the chest of the young child may be made by mixing mustard with wheat flour in the proportion of one to twenty and then making it into a paste. This will usually redden the skin without danger of blistering it. A heavy poultice should never be applied to the

chest, especially when there is difficulty in breathing. A few drops of oil over the surface of the poultice will prevent its adhering to the skin. A piece of very thin paper placed between the poultice and the skin will do the same and enable the poultice to be applied hotter, and aid in the retention of the heat. Tr. iodine is sometimes painted on parts of the chest as a counter-irritant and is sometimes useful. When used it should be painted over a small area until the skin is dark and then not applied again over the same area.

We come now to the mention of certain substances used *ad libitum* in the form of drinks in bronchial affections. With the supervision of the preparation of these demulcent preparations the nurse is naturally entrusted. They are very useful adjuvants to the more vigorous treatment and it has been my experience that ignorance of the preparation of these simple but useful preparations is almost universal among the poor of our cities. These drinks are so inexpensive that they are universally accessible. They are made from starchy or gummy substances. Among these may be mentioned: Flaxseed, althea or marshmallow, gum arabic, slippery elm, arrowroot, licorice, Iceland or Irish moss, and the ordinary starch gruels, *made thin*, such as barley or oatmeal. Some practical directions for the preparation of these drinks may, I think, be useful to you.

Flaxseed Tea.—Pour a quart of boiling water over four heaping tablespoonfuls of whole flaxseed, cover lightly and allow it to steep on the back part of the stove for four hours. Then strain through linen. Flavor with lemon, and sweeten if desired.

Marshmallow Tea.—Take two ounces of dried marshmallow root and one ounce of good raisins; add five large cupfuls of boiling water and boil down slowly to one half. Strain without using pressure. These amounts may be doubled (making twice the quantity) if it proves acceptable to the patient.

Slippery Elm Tea.—Pour a quart of boiling water on two ounces of slippery elm bark; cover lightly and allow it to stand near the fire for three hours. Strain.

Arrowroot Tea.—Mix thoroughly three tablespoonfuls of arrowroot with two tablespoonfuls of white sugar and the peel of a third of a lemon; add a pinch or two of salt and a quart of cold water. Set on the fire and boil for a few minutes.

Gum Arabic Water.—Take a quarter of a pound of white gum arabic, a quarter of a pound of rock candy and a large thinly sliced lemon. Pour onto this a quart of boiling water and, constantly stirring, keep it in a warm place until the gum is dissolved.

Irish or Iceland Moss.—Wash half an ounce of the moss in cold water. Put it into a quart of water and boil gently for fifteen minutes, then strain and sweeten, and flavor with lemon, or white wine may be used if available. All of these preparations may be taken freely and frequently during the day. For use in bronchial or throat affections they are better when taken hot, or warm at least.

To the flaxseed tea licorice may sometimes be added with advantage, in the proportion of half an ounce of the bruised licorice root added before the water is poured on; or two teaspoonfuls of the powered licorice, to the above quantity, added after the tea is made. Gum arabic may also be added to the flaxseed tea if desired. It should be added after the tea is made. The whole gum should be used, *not the powdered acacia.*

We will now briefly consider some of the more common of the pulmonary diseases with which you meet, and that portion of the treatment which may come within a nurse's duty.

Of all these affections, bronchitis in one of its various forms is the most frequently met with. In these cases it is for you to see that the temperature of the room is that proper for this class of case, taking into consideration the age and vitality of the patient, and that, once established, this temperature is kept even, without sudden and unnecessary fluctuations; that the room is not laden with moisture or its atmosphere dried to the point of suffocation; that the diet is simple and nutritious; that proper clothing is worn, especially that the *feet and legs* are kept warm and dry. If pain and soreness in the chest becomes troublesome, as is not infrequently the case, it will devolve upon you to superintend the preparation of a poultice or the application of a liniment. If baths are required, for medicinal reasons in any case, or for cleanliness in cases of some duration, it becomes your duty to see that they are properly employed with due regard to the precautions mentioned under this head. In very acute cases baths should as a rule be avoided.

In cases *with much restlessness* and *exceptionally high fever* a light sponge bath, with a little alcohol added to the water, will not be objectionable, in these acute cases, and will prove grateful and quieting, especially with children. Such baths should be given under your personal supervision, however. Finally, you may greatly assist in the relief of these cases by preparing, or directing the preparation of, one of the demulcent drinks mentioned above. Inhalations are used with great benefit in these cases and may be prepared as already described. Sedative remedies such as benzoin, in the form of the compound tincture, are perhaps more universally beneficial, but sometimes the more stimulating vapor of turpentine is required, or the stimulating and antiseptic action of creosote is useful, especially in chronic or subacute cases.

Chronic bronchitis, as met with in these homes, is one of the most intractable of diseases, and usually requires for its successful treatment a complete revolution in the patient's mode of life. This you can rarely bring about, and it remains for you to approximate success, as nearly as possible, by attempting to secure the cooperation of

the patient and the members of his family in the observance of the "hundred and one" little details of personal and general hygiene, in the faithful observance of which, in conjunction with the special treatment, success is *alone* to be obtained. Perhaps the most pathetic and trying among these cases are those seen in children; chronic or subacute cases that linger for weeks or months; defying all our efforts to relieve them under the stubbornly unfavorable conditions of the home; until some kind fairy carries the little one off on "Country Week," removes the handicap under which it has been struggling, drops it down in the midst of green grass, warm sunshine, pure air and food; and light returns to the eyes, and color to the cheeks, and rest to the tired lungs.

While these children are at home they must be protected from dust; they must have pure air to breathe, day and night, but they must be shielded from strong cold winds and sudden extremes of temperature; they should be out of doors while the sun is high and warm, but they should not be exposed, as a rule, to the cool damp air of evening; they should not be allowed when once in bed, to get up and run to the door or windows, as is frequently the case; the under clothing should be of wool, of medium weight *not heavy,* except in the very hottest weeks of summer, when cotton, preferably with small admixture of wool, may be substituted, the feet especially should be kept dry and warmly clad; the food simple and nourishing, and above all properly prepared. Unless some exceptional reason to the contrary exists, these cases are much benefited by salt baths; warm full and fairly strong salt bath at bedtime and a sponge off in the morning with cool, but not cold water, with a small amount of salt added. This should be done only with the consent of the attending physician, since there may be some reason in the individual case why the procedure would not be advisable.

Chronic bronchitis in patients well along in years, is frequently associated with an emphysema, a relaxation and dilation of the air cells, frequently accompanied by a spasmodic constriction of the small bronchi. This causes great distress in breathing, which is at times very difficult to relieve. Systematic compression of the lower half of the chest, on each *expiration*, over a period of ten minutes three or four times a day, will give these cases a certain amount of relief, in addition to the other treatment. Some relative or friend may be taught to do this very well. Massage of the chest and the respiratory muscles is also sometimes beneficial. In conclusion we may repeat that the element of dust in the atmosphere must be as far as possible eliminated, in every case of bronchitis, in every stage of the disease.

Constipation sometimes incident to the disease and at other times dependent upon the astringent effect of sedative cough mixtures, must be relieved by simple laxatives.

Pleurisy.—The feature which you are sometimes called upon to relieve in this condition, in the absence of the physician, is pain. The sharp pain in the side characteristic of this disease in some of its stages, may be relieved by a small mustard poultice over the site of pain; or tincture of iodine may be painted over the spot. If these measures do not relieve it the pinning of a towel or band tightly about the chest is sometimes effective, or better still an adhesive plaster band around that half of the chest will give relief.

Acute Pneumonia.—In no disease must the nurse be more vigilant than in this. There is not so much left to her own initiative, however, in this disease as in some other pulmonary affections, but she must constantly watch for the signs of pulmonary or cardiac failure and be ready to meet them with the administration of oxygen and the usual stimulants. Deepening cyanosis, increasing difficulty in breathing and the supervening of stupor or coma, are indications for the use of oxygen. Preferable to the use of the mouthpieces coming with the inhaling apparatus is an ordinary glass funnel, of a size dependent upon the age of the patient. The oxygen should be allowed to flow out, as indicated by the water-bottle, quietly and steadily, not violently and wastefully, as I have seen it used. The pain of the initial stage is due to pleurisy and may be somewhat relieved by the application of hot poultices. They should never be large and heavy. Other methods of relieving the pain, such as cupping, or the administration of morphine which sometimes becomes necessary, would hardly be done except by direct order of the physician. If fever is high and delirium is present an ice-cap may be employed.

Acute pneumonia, being a disease of comparatively short duration, we do not usually mind a temperature of considerable degree, provided the patient is in otherwise fair condition. It occasionally becomes necessary, however, to reduce an excessively high fever, which in itself seems to threaten our patient's welfare. This we attempt to do by a cold sponge and, in the absence of effect from this, we may use the cold-pack. Only very rarely should the cold full-bath be employed. For children a hot full bath at 105° F. with a few handfuls of mustard added to the water may be used with benefit. The child should be taken from the bath and, without being dried, is immediately wrapped in a blanket. Profuse perspiration usually occurs and is often followed by restful sleep.

At the end of a pneumonia, during the crisis, when the dyspnea is relieved and the temperature is falling, a period sometimes comes when the heart, which previously has perhaps been working manfully against great odds, fails. Then is the time when the nurse is often called upon to act quickly, intelligently, and vigorously, to rally the failing forces of life. Subcutaneous injections of atropine, nitroglycerin or strychnine in full doses are indicated, and alcohol and caffeine by the mouth. In the case of a child a hot bath

may be given under these circumstances and aromatic spirit of ammonia given by the mouth. A very good stimulant for hypodermic use in children in cases of extreme collapse is ten minims of a solution of camphor 1 in ether 10.

Occasionally changing the position of a patient, will sometimes give much relief to the breathing, and in young children, who do not invariably think to take the posture most comfortable for them, should always be borne in mind by the nurse. It should be remembered that pneumonia is an infectious disease and under certain conditions may be transmitted from one person to another. The sputum should be carefully cared for, and it is an excellent plan to disinfect it as you would tuberculous sputum.

Tuberculosis of the Lungs.—In the world's battle against this treacherous foe you are now taking, in your district work, an active part. It is hardly necessary perhaps to enter into the details of the defensive and offensive methods of warfare waged against this disease. Knowing the source of danger, the lines of defense become fairly well defined and, as might be supposed, are more readily carried out than measures directed toward the subjugation of the disease, once it has invaded the system. Defense of the individuals living in the immediate environment of the source of the tuberculous contagion must be regarded as the first and most important duty of every worker in the army moving against this "great white plague." The victim must be given a bed to occupy alone, and, where possible of course, a room by himself. The sputum should be collected with most scrupulous care. If the slight expense of the folding paper cups with which you are doubtless familiar, is an insurmountable obstacle to their use, an ordinary cup containing a little of a five per cent. solution of carbolic acid solution is perhaps the next best thing. This can be used at home. When on the street small pieces of cotton or tissue paper may be used and placed in a rubber tobacco pouch, which is emptied into the fire on the return home, and the pouch thoroughly scalded and kept for use again. A handkerchief should never be used for any such purpose. The patient should be instructed to hold a handkerchief before the mouth during an attack of coughing, to avoid the diffusion of fine particles of sputum through the atmosphere.

As to the degree to which these precautions are carried out much will depend on your watchfulness and continued admonitions to the patient and those about him; and much, very much, on the character of the patient himself. We must be patient with him. We must not forget that we are demanding from him an expression of the noblest attribute of human kind, the highest of which the human character is capable; the thoughtful, self-forgetting consideration of others in the hour of personal weakness and suffering. Often, however, your hardest battle will be with those you are striving to protect. Affection for the afflicted, the noblest of excuses, will lead to constant and unnecessary violation of those little but potent rules of hygiene on which so much depends. And this brings us to a fact which for several years deterred many who understood the situation from taking active measures against the ravages of this disease. This was the dread lest the general inculcation of the doctrine of the contagious nature of the disease should alienate from the victim even those nearest and dearest to him. Were there ever a danger of such an occurrence, it would be due to the way we taught the truth and not to the truth itself. We must explain to the individuals of the household, that while tuberculosis is a communicable disease, it is not so in the degree in which the majority of other infectious diseases are communicated. Since we cannot exactly foretell the intimate conditions of the system that render it susceptible, certain reasonable precautions are wisely taken against wholesale and entirely unnecessary admission of the germs into the body.

With all possible precautions observed there still remains a certain element of danger for those in constant association with the patient. This danger we can greatly diminish by so fortifying the system with well cooked, nourishing food, fresh air and hygienic measures, as to render it unlikely to be receptive to invading germs.

Here we shall often be greatly handicapped by the bad habits or unhealthy occupations met with among the class of which we are speaking. We can but exert ourselves to the utmost and do the best we can. Accustoming the people to cold morning baths, to regular and sufficient sleep, to the avoidance of colds and bronchial affections, by the wearing of suitable clothing and by the maintainance of dry and warmly clad feet, will all aid in neutralizing these unfavorable conditions. We must not become discouraged by individual instances where all our efforts appear in vain, for the steadily declining death rate, in spite of the modern methods of diagnosis which ensure the certain recognition of all cases of the disease, tells us we are fighting a slow but winning fight.

In the treatment of the victim himself a maximum amount of the most nourishing food, plus fresh air, in as large doses as can be obtained, is imperative. As important as the character of the food is its preparation. Sufficient and regular hours of sleep must be instituted. Unfortunately it is often impossible to obtain the cooperation of these patients in their home, and I personally am becoming more and more convinced that the only hope for them lies in sanatorium treatment. And even in those slight cases that are at present the only ones accepted in our state sanatorium, the marked improvement almost invariably shown is ultimately lost if they return to the life of their homes again. This is especially the case with those moderately pronounced cases, too far along to gain admission to the sanatorium, but really in a favorable stage of the disease, provided the proper conditions of life could be secured for the

patient, *and always maintained.* These patients we may sometimes succeed in sending to the numerous boarding houses at Rutland where the life of the sanatorium is inculcated, and even enforced. The improvement shown by many of these patients is incredible to one who has not witnessed it, and yet I regret to say that again and again I have seen that gain in weight and color, in buoyancy and hope, melt away far more rapidly than it came, on a return to the life at home. I do not believe therefore, that it is wise to induce false hope in these patients by sending them to live for a time under such circumstances, unless there is some probability of their being able to fairly approximate that favorable life during their entire existence.

There are certain symptoms in consumptive cases which it often falls to the lot of the nurse to alleviate, and certain emergencies which chance sometimes orders her to meet. Of these we will now speak. Many of these conditions are of course, strictly speaking, within the province of the physician, but since this is a chronic long continued disease, not receiving frequent visits from the physician, you will often be called upon to relieve the temporary distress of your patient. This may often be done by simple means; applicable without harm to any case, and not involving more radical measures which you would rightly hesitate to employ. The cough, usually a marked feature of the disease, sometimes becomes, by its great excess, a source of much distress and fatigue to the patient. Where the expectoration is abundant the cough is of course necessary for its removal, and no radical measures should be employed to stop it unless the excessive secretion is checked. However, these are not, as a rule, the circumstances under which the cough is distressing. It is where the cough is dry and racking, far in excess of the expectoration, that the greatest distress occurs. Any of the demulcent drinks above mentioned may be given freely and often with benefit, especially if given hot. A small but strong mustard or spice poultice over the upper portion of the sternum may do much to give relief. Painting the spaces above the clavicles with tincture of iodine will sometimes relieve the excess of cough. A hot mustard foot-bath with hot drinks will give relief, especially in the cough that is often very troublesome when the patient first gets into bed at night. This is a very common occurrence. It may be avoided usually by warming the bed previous to the patient's retiring. Inhalations such as have been described in connection with bronchial affections are frequently of great benefit in excessive irritating cough; especially creosote. The excess of cough in individual instances is sometimes due to pleurisy, even where there is no pain. After all other means have failed therefore, the binder or plaster strip may give some relief.

The pain in consumptive cases is usually due to pleurisy and is to be dealt with as with pleurisy from any other cause. Night sweats are often a source of much discomfort. When excessive this symptom usually requires internal medicinal treatment. Some relief may be given, however, by sponging the patient with vinegar, or dilute acetic acid and water, *equal parts,* may be used. Alum dissolved in alcohol in the proportion of half a dram of the alum to the pint of alcohol makes an efficient lotion for the same purpose.

The patient should wear a light weight flannel nightgown which absorbs the moisture better than linen or cotton and is therefore much more comfortable. Fever, if reaching each day to 101° F., or over, should be treated by rest in bed. It is however no contraindication for fresh air, provided the same can be obtained with the patient at rest.

Hemorrhage from the lungs is an emergency which anyone, physician, nurse or layman, may be called upon to meet at any time, not alone in the visibly sick but in the apparently well individual. First and foremost of the measures employed to meet the crisis must be absolute physical and mental rest. Put the victim to bed and isolate him from all disturbance. Cracked ice by the mouth may be given. The cough and the peculiar nervous restlessness often seen in these cases must be relieved by a small hypodermic dose of morphine. Ice may be applied to the upper part of the chest, just under each collar bone. The subsequent care should consist in a light diet, a laxative each day sufficient to freely move the bowels and a continuance of the absolute physical rest many days after the cessation of the hemorrhage. In profuse hemorrhage it is useless to attempt the inhalation of astringent substances. Where the bleeding is slight, a spray such as the following may be tried: Take alum, six grains; water, three ounces, or Monsel's Solution ten drops in two ounces of water. Both are to be used in a hand atomizer. A teaspoonful or two of the fluid extract of ergot may be given internally, immediately, but the remedy that promises most relief is the extract of the suprarenal gland; and so important is every moment in meeting severe hemorrhage that I think it an excellent plan for a nurse who is working with many phthisical cases to carry a few tablets, or some of the powder, with her. It is given in the dose of three to five grains and is to be placed dry *on the tongue* and not swallowed but held in the mouth and allowed to dissolve. It may be repeated every thirty minutes, for three or four doses if necessary. Do not give stimulants in pulmonary hemorrhage. In closing the subject it may be added that in the case of any pulmonary disease it is an excellent plan to disinfect the expectoration or to exercise care against its dissemination broadcast by the patient. It has been found that many cases of bronchitis, even when semi-chronic, are due to the influenza bacilli, and there can hardly be a doubt that from such individuals epidemics of acute influenza may originate. In other cases other organisms are present, some of which, especially the streptococci and the

pneumonia organisms, are a constant menace to the well and may give rise to other than pulmonary disease.

MEDICAL PROGRESS.

PHYSIOLOGY.

The Effect of Caffeine upon the Vagus Center.—In small and medium doses intravenously injected into dogs, caffeine, stimulates the vagus center, according to G. Swirski, (*Pflüger's Archiv*, August 22, 1904). This is, however, an inconstant phenomenon, failing in forty per cent. of the cases. The fall in blood-pressure brought about by small intravenous injections of caffeine, is caused by a lowering of the tone of the vasomotor center by reflexaction, without the aid of the depressor nerves. The blood-pressure-raising action of caffeine is in greatest part due to a *direct stimulation* of the vasomotor center in the medulla, and to a less degree of the centers in the spinal cord. Large doses of caffeine in dogs had no appreciable effect in the heart muscle.

The Activities of Zymase and Endotryptase in Killed Yeast Cells.—The juice expressed from yeast contains a sugar-splitting ferment (zymase), a proteolytic ferment (endotryptase), and in addition inverting, diastatic reducing, and other ferments. T. Gromow and O. Grigoriew (*Hoppe-Seyler's Zeitsch.*, August 17, 1904), in an investigation of the various conditions which affect the workings of zymase and endotryptase, discover a number of facts of eminent importance from the general standpoint of the physiological significance of ferments. Killed yeast cells are found in commerce under the name "zymin," which possesses all the characteristics of live yeast except the power of growth and multiplication. Its proteolytic ferment, endotryptase, is a powerful one, whose action is strongly inhibited by saccharose, glucose, lactose, mannite and glycerin. The more concentrated the solution of saccharose, the greater is its inhibitory action. This inhibition of the above substances is in all probability favorable to the synthesis of proteids; the decomposition products of albumin inhibit the further destruction of the latter. Saltpeter and calcium chloride stimulate the action of endotrytase, while quinine and alcohol inhibit it. Substances which inhibit the latter, stimulate the action of zymase, while those that accelerate the work of endotryptase, inhibit the activity of zymase.

Inhibition of the Action of Physostigmine, by Calcium Chloride.—The study of drug antagonism is valuable from the standpoint of physiology as well as therapeutics. S. A. Matthews and O. H. Brown (*Am. Jour. of Physiol.*, October 1, 1904), have made an important contribution to this subject. They allude to the results obtained by Loeb in preventing by means of calcium of trontium chloride, the marked muscular twitchings produced by sodium citrate, tartrate, oxalate, phosphate, and barium chloride, when injected into the lymph spaces of the frog. MacCallum has shown that the marked intestinal peristalisis produced by many of the above salts, in mammals, can be inhibited by the injection of calcium chloride. Fisher found that the glycosurin produced by electrolytes is inhibited by a sufficient amount of calcium chloride. The antagonism between atropin and pilocarpin, atropine and nicotine, and atropin and physostigmin is also alluded to. S. A. Matthews has shown that the convulsions produced in tetanus are inhibited by an intravenous injection of a combined salt solution in which calcium chloride is present. The authors investigated the effect of calcium upon the action of physostigmin, in dogs. They found that the action of the latter drug in producing, (1) the contractions of the intestine, and (2) the tremors of the voluntary muscles, is counteracted and inhibited by calcium chloride; (3) the increased salivary secretion is, at least partly, counteracted and inhibited by the calcium chloride.

The Activating Substance of the Pancreas in the Metabolism of Carbohydrates.—In 1903 O. Cohnheim found that the muscles of dogs and cats contain a glycolytic ferment, which in itself is inert but is rendered active by means of the pancreas. The author (*Hoppe-Seyler's Zeitsch.*, August 17, 1904), has succeeded in isolating the principle of the pancreas which is responsible for the activation of the glycolytic ferment of the muscles. This pancreatic constituent is not affected by boiling, is soluble in water and 96 per cent. alcohol, but not in ether, and in this account is to be distinguished from proteids, ferments and, above all, from most of the constituents of the pancreas. The solubilities of the pancreatic activator, its resistance to boiling and its solubility in alcohol, show that it is no ferment, and place it in the same rank with the other and better known internal secretions, namely, adrenalin, iodothyrin and secretin. As regards the behavior of this pancreatic activator, the surprising fact is revealed that if to a constant mixture of muscle-juice and sugar, increasing amounts of pancreas be added, the action of the latter at first increases and then diminishes. This is the case whether one use the entire pancreas, the alcoholic extract of boiled or unboiled pancreas, or alcoholic extracts of the proteids to which the activator is united. The maximum of glycolytic action is found in the combination of 75 gms. muscle and 0.8 gm. pancreas. On the addition of 2 gms. pancreas, the action ceases entirely. What is the explanation of this peculiar phenomenon? One might consider that the pancreas contains two bodies, the one accelerating and the other inhibiting. Against this supposition is the fact that the phenomenon occurs with the use of the entire pancreas to the same degree as with the use of the various alcoholic extracts. The two bodies would then have the same solubilities, and yet at first the one, and later the other would act. A good analogy is furnished by the phenomenon termed by Ehrlich the "Diversion of the Complements." Neisser and Wechsberg have found that in the destruction of bacteria by immune sera, in which the cooperation, if amboceptor and complement is necessary, the presence of an excess of amboceptor inhibits, and in certain circumstances, entirely stops the action. It would appear as if the excess of amboceptor, by uniting with the available complement, prevents that union of bacteria, amboceptor and complement, which is necessary in the complete destruction of the bacteria. Cohnheim has found that blood-serum itself contains an activator like that of the pancreas, and muscles containing blood, show without the further addition of pancreas, the phenomenon of glycolysis.

The Fate of Glycocoll Intravenously Injected.—A single injection of considerable amounts of glycocoll into the blood of the dog, causes, according to S. Salaskin and K. Kowalewsky (*Hoppe-Seyler's Zeitschrift*, August 17, 1904) an increased ammonia content in the blood. The latter gets rid of the glycocoll very quietly, eliminating it partly, but to a slight extent, by means of the urine, and partly transfering it to the tissues. The fact that the glycocoll, under the conditions of the experiment, cannot be recovered from the tissues, would suggest that it there under-

goes certain transformations. It is possibly split up with the production of ammonia, which would account for the appearance of ammonia in the blood.

The Question of Hemagglutinins.—The isolation of distinct chemical substances, the agglutinins, has not yet succeeded, according to A. BEXHEFT (*Pflüger's Archiv*, August 15, 1904). Belief in the chemical individuality of these substances would require a numerical relationship between the agglutinating and agglutinated substances. The author found that by mixing ox-blood with corresponding amounts of the blood of swine, substances may be obtained which agglutinate the red blood capsules of the latter. Success in the procedure required the use of equal quantities of both kinds of blood. The agglutinins are contained in the serum, for if this be decanted from the clump of red blood cells, it will still be found capable of agglutinating the cells. No agglutinins can be obtained from the agglutinated corpuscles of the swine, by means of a physiological salt solution. From these results the author draws the conclusions that in ox-blood there is present a distinct substance capable of agglutinating the red blood cells of the pig; and that one may probably have to deal with a chemical union of this substance with the red ox-blood cells, since it cannot be recovered by simple dissolving media, such as physiological salt solution.

The Occurrence of Acid-Amides in the Urine in Pathological Conditions.—The normal human urine contains the faintest traces of acid-amines, according to A. IGNATOWSKI (*Hoppe-Seyler's Zeitsch.*, August 17, 1904). Even after the subcutaneous injection of glycocoll, no acid-amines are found in the urine. But considerable quantities of this substance are found in the latter in cases of gout. In seven cases of gout glycocoll was regularly present, and in three of the same cases, other acid-amines, probably leucin and asparaginic acid were found. Acid-amines are also present in pneumonia, particularly at the crisis and in leucemia.

The Inorganic Constituents of Tumors.—Following the discovery by Loeb that the health of the tissues is dependent upon the chemical equilibrium of definite inorganic substances in their environment, one naturally expects numerous researches into the inorganic chemistry of tissues which are the seat of pathological processes. S. P. BEEBE (*Am. Jour. Physiol.*, October 1, 1904) is investigating the chemistry of malignant growths. He has already made an analysis of the inorganic constituents of tumors, with certain interesting results. He admits that ash analyses do not show the conditions in the living tissues; the metals may be present in the cell as iron proteid combinations, but the amount of calcium relative to potassium or sodium, for instance, can be determined by such an analysis, and recent work has demonstrated that the relative proportion of these elements may determine the degree of activity in such important structures as glands and muscles. It is probable, he believes, that the soluble, easily diffusible salts have much to do with maintaining the proper osmatic environment of a cell during the continuous and varied changes in the surrounding medium. They are, therefore, important aids in the nutritional processes of a tissue. He gives the results obtained from the ash analysis of nine neophlasms, one of which was benign, and determines the percentage of N, S, P, Fe, CaO, K and Na, contained in the ash. The N varied from 0 to 12 per cent., the difference probably depending upon the variations in the amount of fat. In the case of a carcinoma of the liver, secondary to a growth in the pancreas, the nitrogen was precisely the same as in the normal tissue surrounding it. The growth having the smallest amount of unclear material, the uterine fibroid has likewise the smallest amount of phosphorus. The ratio between calcium, potassium and sodium furnish the most interesting results of the work. Two badly degenerated tumors contained about ten times the amount of calcium found in the fresh, vigorously growing tumors, and there was at the same time a much smaller content of potassium. The analyses indicate that degeneration is accompanied by an increase in calcium or decrease in potassium; the ratio between the two is altered by a relative increase in the calcium. The conditions found appear to be in accord with what is known regarding the physiological rôle of calcium and potassium. In their effects on vital phenomena they stand opposed. The intense activity brought about by the potassium ion in the gland cells of the intestine, as shown by MacCallum, is stopped by the calcium ion. Their effects also on muscle tissue is an antagonistic one. In the degenerated tissues the vital activity has ceased, only autolysis is going on, and in these tissues is found a large amount of calcium. The fresh, vigorous tissues, having active nutritive changes, contain a relatively large amount of the ion which has the power to call forth vital activity. The presence of potassium seems to be associated in some way with the remarkable nutritional activities of tumors, of which rapid growth is one manifestation. The author believes it will be interesting to know whether, as in the glazed cells of the intestine, the continued exposure of the cells in a rapidly growing tumor to the influence of the calcium ion would be followed by an inhibition of the intense metabolic activity associated with the preponderance of the potassium ion.

Atypical Cases and Dust Infection.—Under this caption there is described by ROBERT HESLER (*Am. Med.*, Oct. 1, 1904), a symptom-complex which is fairly uniform or constant and entitled to the name of a distinct and independent disease. By "dust disease" is meant not the specific diseases which can be transmitted by the agency of dust or may follow the inhalation of dust, such as pneumonia, typhoid, tonsillitis, bronchitis, etc., but those hitherto vague and ill-defined symptom-complexes that are variously referred to as colds, biliousness, migraine, hypochondria, etc., or as atypical cases of influenza, rheumatism, gastritis, neurasthenia, auto-intoxication. Cases of dust disease are to be especially looked for under and separated from recognized diseases in which "rheumatic and gouty diatheses" play a part, also among cases spoken of as nervous; likewise in cases in which there are frequent alimentary or respiratory tract disturbances. It is most prevalent in crowded cities; country people may be attacked on going to the city. It is absent among Arctic explorers and weather observers on high mountains, but these on returning home may be attacked again. The cases may be divided into groups depending on which part of the body is chiefly affected. There is marked or recognizable pathological lesion. The causative factor is infective dust and whether it produces systemic infection, or a septic intoxication or sapremia, is immaterial from the clinical standpoint. Care must be taken not to confound the symptoms at first with those of other specific diseases which they may resemble. When once recognized, the most important point in treatment is a change of atmosphere. A number of cases are detailed to support the author's contentions.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, OCTOBER 22, 1904.

A LESSON FROM THE ORIENT.

There is food for profound reflection and incentive for vigorous action in the paper read before the International Congress of Military Surgeons in St. Louis, by Dr. Louis L. Seaman, of New York. We are, as a nation, not so much more astute than the holy men of the Middle Ages, who held themselves aloof in their monasteries and prayed the Divine Hand to check the tide of plague and death that rolled in the wake of war. We accept as a concomitant of war disastrous losses through preventable disease, and feel that when we have properly expressed our dismay and disgust at the corruption of the government and the shortsightedness of the powers that be, we have done all we can in behalf of civilization.

Dr. Seaman, who was a major and surgeon in the United States Volunteers during the war with Spain, has just returned from a recent observation of Japanese sanitary and surgical methods in the war with Russia. From his report it seems that no obstacle has been too great to overcome, no detail too trifling to be observed, with the result that there has been during this six months of terrible fighting and exposure in a foreign country only a fraction of one per cent. loss from preventable disease. Contrast this with the results in our own Spanish War. The actual deaths from bullets was only 268 while the deaths from disease, in camps far from the seat of war, amounted to 3,682 more than fourteen times as many.

Were we to move an army to the front to-morrow, our record would probably be the same, and yet the Japanese have only recently learned their lessons from us, and from the sources from which we draw our science. But the difference is, they believe and *do*, while we believe and don't do.

Witness the way in which they act upon the principle that an army's fighting power depends upon the quality of its rations and the observance of hygiene. The medical officer is everywhere prominent. He is with the scouts, making microscopical and chemical tests of the water and the soil, labeling wells, so that the army shall drink no contaminated water. He examines towns, and puts a cordon around any quarter where there is infectious disease. The medical officer also accompanies foraging parties, testing fruits and vegetables sold by natives, and if the fruit requires cooking or the water boiling, or if there is any taint suspected, notices to that effect are posted, and such is the discipline, from commanding officers to the rank and file, that obedience to his orders is absolute.

The medical officer also supervises the personal hygiene of the camp. He teaches the men how to cook, how to bathe, how to cleanse the finger nails to free them from bacteria, as well as how to live in general a healthy, vigorous life, and it is a part of the soldier's routine to carry out these instructions in every particular.

Long before there was any outbreak of hostilities the medical officer was with the advance agents of the army, testing provisions that were being collected for troops, and as a consequence the medical officer of the Japanese army has successfully prevented thousands of cases of intestinal diseases, diarrheas, dysenteries, typhoid and malarial fevers.

From the economic standpoint it has been estimated that whereas Russia will probably lose four men by disease for every one killed in battle, Japan will probably be able, by the better health of her army, to neutralize the advantage of her enemy's superior numbers.

From the standpoint of humanity, of common sense, of civilization, it is nothing short of criminal to permit such ravages of typhoid as are at

goes certain transformations. It is possibly split up with the production of ammonia, which would account for the appearance of ammonia in the blood.

The Question of Hemagglutinins.—The isolation of distinct chemical substances, the agglutinins, has not yet succeeded, according to A. BEXHEFT (*Pflüger's Archiv*, August 15, 1904). Belief in the chemical individuality of these substances would require a numerical relationship between the agglutinating and agglutinated substances. The author found that by mixing ox-blood with corresponding amounts of the blood of swine, substances may be obtained which agglutinate the red blood capsules of the latter. Success in the procedure required the use of equal quantities of both kinds of blood. The agglutinins are contained in the serum, for if this be decanted from the clump of red blood cells, it will still be found capable of agglutinating the cells. No agglutinins can be obtained from the agglutinated corpuscles of the swine, by means of a physiological salt solution. From these results the author draws the conclusions that in ox-blood there is present a distinct substance capable of agglutinating the red blood cells of the pig; and that one may probably have to deal with a chemical union of this substance with the red ox-blood cells, since it cannot be recovered by simple dissolving media, such as physiological salt solution.

The Occurrence of Acid-Amides in the Urine in Pathological Conditions.—The normal human urine contains the faintest traces of acid-amines, according to A. IGNATOWSKI (*Hoppe-Seyler's Zeitsch.*, August 17, 1904). Even after the subcutaneous injection of glycocoll, no acid-amines are found in the urine. But considerable quantities of this substance are found in the latter in cases of gout. In seven cases of gout glycocoll was regularly present, and in three of the same cases, other acid-amines, probably leucin and asparaginic acid were found. Acid-amines are also present in pneumonia, particularly at the crisis and in leucemia.

The Inorganic Constituents of Tumors.—Following the discovery by Loeb that the health of the tissues is dependent upon the chemical equilibrium of definite inorganic substances in their environment, one naturally expects numerous researches into the inorganic chemistry of tissues which are the seat of pathological processes. S. P. BEEBE (*Am. Jour. Physiol.*, October 1, 1904) is investigating the chemistry of malignant growths. He has already made an analysis of the inorganic constituents of tumors, with certain interesting results. He admits that ash analyses do not show the conditions in the living tissues; the metals may be present in the cell as iron proteid combinations, but the amount of calcium relative to potassium or sodium, for instance, can be determined by such an analysis, and recent work has demonstrated that the relative proportion of these elements may determine the degree of activity in such important structures as glands and muscles. It is probable, he believes, that the soluble, easily diffusible salts have much to do with maintaining the proper osmatic environment of a cell during the continuous and varied changes in the surrounding medium. They are, therefore, important aids in the nutritional processes of a tissue. He gives the results obtained from the ash analysis of nine neophlasms, one of which was benign, and determines the percentage of N, S, P, Fe, CaO, K and Na, contained in the ash. The N varied from 9 to 12 per cent., the difference probably depending upon the variations in the amount of fat. In the case of a carcinoma of the liver, secondary to a growth in the pancreas, the nitrogen was precisely the same as in the normal tissue surrounding it. The growth having the smallest amount of unclear material, the uterine fibroid has likewise the smallest amount of phosphorus. The ratio between calcium, potassium and sodium furnish the most interesting results of the work. Two badly degenerated tumors contained about ten times the amount of calcium found in the fresh, vigorously growing tumors, and there was at the same time a much smaller content of potassium. The analyses indicate that degeneration is accompanied by an increase in calcium or decrease in potassium; the ratio between the two is altered by a relative increase in the calcium. The conditions found appear to be in accord with what is known regarding the physiological rôle of calcium and potassium. In their effects on vital phenomena they stand opposed. The intense activity brought about by the potassium ion in the gland cells of the intestine, as shown by MacCallum, is stopped by the calcium ion. Their effects also on muscle tissue is an antagonistic one. In the degenerated tissues the vital activity has ceased, only autolysis is going on, and in these tissues is found a large amount of calcium. The fresh, vigorous tissues, having active nutritive changes, contain a relatively large amount of the ion which has the power to call forth vital activity. The presence of potassium seems to be associated in some way with the remarkable nutritional activities of tumors, of which rapid growth is one manifestation. The author believes it will be interesting to know whether, as in the glazed cells of the intestine, the continued exposure of the cells in a rapidly growing tumor to the influence of the calcium ion would be followed by an inhibition of the intense metabolic activity associated with the preponderance of the potassium ion.

Atypical Cases and Dust Infection.—Under this caption there is described by ROBERT HESLER (*Am. Med.*, Oct. 1, 1904), a symptom-complex which is fairly uniform or constant and entitled to the name of a distinct and independent disease. By "dust disease" is meant not the specific diseases which can be transmitted by the agency of dust or may follow the inhalation of dust, such as pneumonia, typhoid, tonsillitis, bronchitis, etc., but those hitherto vague and ill-defined symptom-complexes that are variously referred to as colds, biliousness, migraine, hypochondria, etc., or as atypical cases of influenza, rheumatism, gastritis, neurasthenia, auto-intoxication. Cases of dust disease are to be especially looked for under and separated from recognized diseases in which "rheumatic and gouty diatheses" play a part, also among cases spoken of as nervous; likewise in cases in which there are frequent alimentary or respiratory tract disturbances. It is most prevalent in crowded cities; country people may be attacked on going to the city. It is absent among Arctic explorers and weather observers on high mountains, but these on returning home may be attacked again. The cases may be divided into groups depending on which part of the body is chiefly affected. There is marked or recognizable pathological lesion. The causative factor is infective dust and whether it produces systemic infection, or a septic intoxication or sapremia, is immaterial from the clinical standpoint. Care must be taken not to confound the symptoms at first with those of other specific diseases which they may resemble. When once recognized, the most important point in treatment is a change of atmosphere. A number of cases are detailed to support the author's contentions.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, OCTOBER 22, 1904.

A LESSON FROM THE ORIENT.

There is food for profound reflection and incentive for vigorous action in the paper read before the International Congress of Military Surgeons in St. Louis, by Dr. Louis L. Seaman, of New York. We are, as a nation, not so much more astute than the holy men of the Middle Ages, who held themselves aloof in their monasteries and prayed the Divine Hand to check the tide of plague and death that rolled in the wake of war. We accept as a concomitant of war disastrous losses through preventable disease, and feel that when we have properly expressed our dismay and disgust at the corruption of the government and the shortsightedness of the powers that be, we have done all we can in behalf of civilization.

Dr. Seaman, who was a major and surgeon in the United States Volunteers during the war with Spain, has just returned from a recent observation of Japanese sanitary and surgical methods in the war with Russia. From his report it seems that no obstacle has been too great to overcome, no detail too trifling to be observed, with the result that there has been during this six months of terrible fighting and exposure in a foreign country only a fraction of one per cent. loss from preventable disease. Contrast this with the results in our own Spanish War. The actual deaths from bullets was only 268 while the deaths from disease, in camps far from the seat of war, amounted to 3,682 more than fourteen times as many.

Were we to move an army to the front to-morrow, our record would probably be the same, and yet the Japanese have only recently learned their lessons from us, and from the sources from which we draw our science. But the difference is, they believe and *do*, while we believe and don't do.

Witness the way in which they act upon the principle that an army's fighting power depends upon the quality of its rations and the observance of hygiene. The medical officer is everywhere prominent. He is with the scouts, making microscopical and chemical tests of the water and the soil, labeling wells, so that the army shall drink no contaminated water. He examines towns, and puts a cordon around any quarter where there is infectious disease. The medical officer also accompanies foraging parties, testing fruits and vegetables sold by natives, and if the fruit requires cooking or the water boiling, or if there is any taint suspected, notices to that effect are posted, and such is the discipline, from commanding officers to the rank and file, that obedience to his orders is absolute.

The medical officer also supervises the personal hygiene of the camp. He teaches the men how to cook, how to bathe, how to cleanse the finger nails to free them from bacteria, as well as how to live in general a healthy, vigorous life, and it is a part of the soldier's routine to carry out these instructions in every particular.

Long before there was any outbreak of hostilities the medical officer was with the advance agents of the army, testing provisions that were being collected for troops, and as a consequence the medical officer of the Japanese army has successfully prevented thousands of cases of intestinal diseases, diarrheas, dysenteries, typhoid and malarial fevers.

From the economic standpoint it has been estimated that whereas Russia will probably lose four men by disease for every one killed in battle, Japan will probably be able, by the better health of her army, to neutralize the advantage of her enemy's superior numbers.

From the standpoint of humanity, of common sense, of civilization, it is nothing short of criminal to permit such ravages of typhoid as are at

present threatening the German army and worked such havoc among the English in the Boer war. It is bad enough for intelligent men to lead their comrades on to human slaughter, but it is worse for scientific men and a civilization that boasts that it depends upon science, idly to watch its compatriots walking into preventable pitfalls of disease.

We may learn a lesson from the artistic sense of proportion and the exquisite attention to detail of our Japanese friends. It is not only those who know how to contrive death for the greatest number that are put in command, but those who know how to prevent death to the greatest number; and the system of prevention is deemed as worthy of detailed care as the system of drill and attack.

Shall we, as a nation, learn this lesson which Japan has taught? Or shall we still go on shrugging our shoulders, dividing the blame between the corruption of officials and the stupidity of the rank and file?

WOOD ALCOHOL.

The lamentable state of public and private morals in its disregard of the life and happiness of others within the last week has been brought sharply to the fore in a manner that, we hope, may be highly salutary.

It seems to need the sacrifice of human lives to stir our busy people to the recognition of dangers that have for years been pointed out by the profession, whose warnings, however, have fallen on careless and unheeding ears.

The arrest of certain fraudulent drug dealers for the adulteration and placing on sale of highly valuable and at the same time extremely dangerous drugs has been referred to. Deaths, due to the use of the substituted wares, have no doubt occurred, but they have usually taken place in the sick chamber, when such a result might have been possible from disease. The harm which this criminal business has done is not measurable, but it exists.

In the case, however, of a precisely similar type of adulteration, namely, the substitution of cheaper wood alcohol for the more expensive grain alcohol in whisky, brandy, gin and other liquors, death has resulted in a number of instances, and happily has called active attention to a form of adulteration that has flourished for many years. In this case, as in the former, the guilty parties have grown greedy in their nefarious work, and instead of making ten per cent. acetanilid mixtures in their drugs, or five per cent. methyl alcohol substitutions, they have grown bolder and bolder, adding more and more of the cheaper grades of material, until finally the result of their work has become a public scandal.

Pharmacologists have told us with reference to the so-called marsh gas series of alcohols, methyl, ethyl, propyl, butyl, amyl, etc., that with the addition of the carbon and hydrogen atoms the toxicity of the compounds increases, and older chemists laid so much stress on the higher alcohols, collectively denominated fusel-oil, that heretofore practically all tests for purity have concerned themselves with these butyl and amyl compounds. Since the manufacture of synthetic wood alcohol, however, this material has been used in larger and larger quantities as an adulterant. Lacking most of the telltale odor of the older natural product, its use has escaped the vigilance of the average consumer.

Although methyl alcohol, if we are to believe the pharmacologists, is thought to be less poisonous than ethyl alcohol, nevertheless it is to be borne in mind that up to the present time not much is known of the pharmacology of the synthetic product, and there is little doubt that the wood alcohols of synthesis are not uniform.

The early researches of Dujardin-Beaumetz and Audigé with natural wood alcohol showed that this alcohol was about one-half the strength of ethyl alcohol, and later observers have confirmed the earlier findings; but it was first shown by Pohl and corroborated by Joffroy and Serveaux that methyl alcohol did not break down, as does ethyl alcohol, and even the higher members of the series, into acetic acid and simpler products, but that it remains for a comparatively long time in the organism, and that if it be taken for a continued period this slow oxidation and slow elimination permit a cumulative action and thereby bring about paralysis and death. Thus animal experiments have shown that ethyl alcohol and even amyl alcohol may be given for weeks or even months at a time and in narcotic dosage without causing death, because of the steady and comparatively rapid oxidation and elimination, whereas, with methyl alcohol the animals perished if the dosage was continued at the narcotic point for a week. Intense fatty degeneration of the liver has been a constant finding in these experimental studies.

A point of further difference has been found in the more intense action of wood alcohol on the

eye. Here its toxic action manifests itself in a most intractable form of blindness.

The extensive series of cases of this form of poisoning now being published by Drs. Buller and Casey Wood (*Journal American Medical Association*, October 1, 8, 15, *et seq.*) brings into prominence how many may be the sources of poisoning from this form of alcohol. Jamaica ginger, essence of lemon, essence of peppermint, witch-hazel, varnishes, turpentines, and colognes and scores of preparations are known to contain it.

The New York City Board of Pharmacy has not been as unmindful of its duty, we believe, as has the chemical department of our City Health Department. For some years the pharmacists of the city have been persistently followed up and prosecuted if wood alcohol has been found in any of the official pharmacopœial preparations calling for grain alcohol. The Board of Pharmacy has not always had the hearty support of the judiciary, which, to our regret, too often needs the same lessons that an ignorant public needs to awaken it to its duties, but notwithstanding such drawbacks, efficient service has been rendered by this body. If our Health Department had been as alive to its opportunities in the matter of testing alcoholic liquors in our city saloons, fewer deaths might have resulted, and this branch of the city work might have demonstrated its usefulness in as convincing a manner as has the more active medical service.

NEW YORK STATE MEDICAL ASSOCIATION MEETING.

The twenty-first Annual Meeting of the New York State Medical Association has been in session during the past week. One of the most interesting features of the meeting was the formal reception of the news that the long-looked-for, much-hoped-for, union of the two medical organizations of this State has not taken place, as was anticipated, and cannot take place until after the change in the by-laws, which will not be operative for at least a year.

Under the constitution and by-laws of the New York State Medical Association, no proper formula for the calling of a regular meeting of State or county associations was embodied. As a consequence, the action of the committees of the two State organizations was upset by the suit of a single member of the Association who claimed that proper notice of the proceedings had not been given him, nor did he wish to agree to the proposed union. The necessary change in the by-laws has been proposed, but this must lie over in the Association for a year, and until formal action is taken upon it no further steps for the union of the two societies can be taken.

This seems to be an unfortunate delay. We feel, as do the vast majority of the members of the medical profession in New York, that union of the two organizations is eminently desirable and is sure to bring good results in its train. On the other hand, we are convinced that none but good results will follow, though there are still some who think that certain evils may creep in. We are sorry that a mere legal quibble should render impotent, for a time at least, all the efforts that have been made in recent years to bring about so desirable a consummation as the corporate union of the members of the regular medical profession in the Empire State. We agree with the President of the Association, who, in his annual address stated emphatically his hope that union would take place just as soon as it could legally be accomplished, and that in the meantime both organizations should strive to interest as many physicians as possible in the idea that membership in medical organizations is sure to bring with it, not only information and help for practice, but stimulus and inspiration for scientific and clinical work and fraternal good feeling, both in professional duties and in social life.

This year's meeting of the State Medical Association has not been as successful, either from the scientific or social standpoint as those of previous years. This is not difficult to understand, and is no fault at all, either of the members of the Association or of the committee in charge of the program. Until a very short time ago it was thought that there would be no meeting of the New York State Medical Association this year, but that the united Society and the Association would hold a common and enthusiastically successful meeting. Under the circumstances the committee have done very well not to allow the meeting to lapse for the present year and to go on, in spite of discouragement, with the work of the Association.

Many of the papers read at the meeting proved of great interest and were discussed very suggestively. Some papers not on the program, but read by members, proved to be especially valuable. The present year's meeting by no means represents the true spirit nor the forceful ability of the Association, but the new board of of

ficers promises to make the next year of the Association quite as successful as any in its history, if there will not even be an actual advance in scientific and social features.

ECHOES AND NEWS.

NEW YORK.

Officers of the New York State Medical Association.—The following officers were elected by the New York State Medical Association for the ensuing year: President, Dr. J. Riddle Goffe, of New York; Vice President, Allan A. Jones, of Buffalo; Secretary, Charles Ira Redfield, of Middletown; Treasurer, Frederick A. Baldwin, of New York; Chairman of Committee of Arrangements, F. W. Loughran, of New York; Chairman on Committee of Legislation, Dr. E. Elliott Harris, of New York; Chairman of the Committee on Library, Alexander Lambert, of New York; Chairman of Committee on Public Health, Louis C. Ager, of Brooklyn; Chairman of Publication Committee, C. E. Denison, of New York; Chairman of Nominating Committee, Dr. Wisner R. Townsend, of New York; Delegates to the American Medical Association, Dr. Everard D. Ferguson, of Troy, N. Y. and Dr. Wisner R. Townsend, of New York.

Gifts to Charity Hospitals.—By his will, filed for probate in the Surrogate's office recently, Moritz M. Frankenthal, of New York, bequeathed $1,000 to each of the following named charities: Mount Sinai Hospital, Hebrew Orphan Asylum Society, Montefiore Home for Chronic Invalids, Hebrew Infant Asylum, and the Home for Aged and Infirm Hebrews.

A First Prize for New York.—It was announced by Secretary Murray, of the Department of Health, that the Department had been notified by the officials of the Louisiana Purchase Exposition at St. Louis, that the superior jury of awards had awarded the grand prize to the city of New York, for their exhibit of health charts and statistics.

Pneumonia Commission to Meet.—The commission appointed by the Health Board to study pneumonia, and endeavor to find means of preventing it, will hold its first meeting at the Health Board on Saturday, October 22. The commission will be made up of prominent bacteriologists from Philadelphia, Baltimore, Boston, Chicago and this city. After a business session they will probably be entertained at dinner at the University Club by Health Commissioner Dr. Thomas Darlington and Dr. H. M. Biggs, chief medical officer of the department. Dr. Darlington is having statistics of pneumonia for the last twenty years prepared from the department records and charts, showing the steady increase in the number of cases.

To Keep City Water Pure.—Not satisfied with his hurried investigation of the watershed conditions on Saturday, Mayor McClellan has told Dr. Thomas Darlington, Commissioner of the Board of Health, that he would soon make another trip through the Mount Kisco, Bedford, Katonah and Lake Mahopac sections. It is probable that the tour will be made in the Mayor's automobile next Saturday, weather permitting. Dr. Darlington, however, has pronounced ideas regarding the methods which should be adopted to free the Croton watershed from all sources of contamination. He is reported as having said that he did not believe in copper sulphate nor filtration systems and that the best way is to keep the water pure from the first. This can only be accomplished by seeing that the territory from which the supply is drawn is free from all the evils which have recently been discovered in the Croton watershed. Throughout the entire section of the watershed there is much building going on. This indicates an influx of persons who intend to reside there. The demand for property is increasing every year. There can be but one result—the section will become more densely populated each year, and the problem of protecting from contamination the network of small streams will soon become impossible of solution. The wholesale purchase of land in the watershed wherever there are dwellings near the lower levels of the valley, or to prevent the erection of new dwellings, would of course entail great expense upon the city. Land is held at an almost uniform price of $100 an acre, and to buy the 360 square miles in the watershed would cost more than $200,000,000. But this is what must be done eventually, if the source of New York's water supply is to be kept clean and wholesome. It seemed to him that it was not altogether a question of present necessity, but that future generations should be protected by action taken now. What will the residents of this city do twenty years or even ten years from now unless some means is devised to guard the purity of their water? Repeated efforts to obtain convictions for violations of the present laws to protect the watershed have invariably failed. When clear cases against farmers who allowed manure heaps to drain into the streams, had been made out, it was found impossible to find grand juries, made up of their neighbors, to indict them. More legislation is needed before legal restraint can be made effective.

Change at Bellevue Hospital.—The Board of Trustees of Bellevue and Allied Hospitals has received the resignation of Dr. George B. Fowler, who for many years has been the attending physician to the Fourth Division. The vacancy will be filled in the near future by some member of the medical profession of New York City who is not connected with any of the colleges, the Fourth Division in Bellevue always having been an open one, that is, not being in any way under the control of the faculties of the several colleges. Applications for the position may be made to Mr. James K. Paulding, Secretary of the Board of Trustees of Bellevue and Allied Hospitals. It may be explained that Mr. Paulding is also Chairman of the Conference Committee, consisting of two members from the Medical Board and two from the Board of Trustees. Before this Committee all names will be brought for con-

PHILADELPHIA.

Free Use of Antitoxin Urged.—Diphtheria is now prevalent in the city, the new cases for the past week showing a considerable increase over those of the preceding one. Chief Abbott, of the Bureau of Health, urges the preventive use of antitoxin to aid in limiting the spread of the disease. The city laboratory manufactures enough antitoxin to supply every physician free of charge with all for which he has need. It may be secured at any police station by the physician agreeing to furnish the Bureau of Health a history of the case in which it was employed.

Animal House for Medical College.—Contract has been let for the construction of a $40,000 vivarium for the medical department of the University of Pennsylvania. The building will be of the most approved type. Work is to be begun immediately.

Ask for Dental Corps in Army.—The Fifty-eighth Annual Meeting of the Pennsylvania Association of Dental Surgeons was held at the Continental Hotel during the past week. A resolution was passed endorsing the movement of the National Association to secure the placing of a corps of commissioned dental surgeons in the United States Army.

Stereoscopic Skiagraphy.—At the Philadelphia County Medical Society, October 12, Dr. M. K. Kassabian read a paper on "The Value of Stereoscopic Skiagraphy" and gave a practical demonstration of the principles involved. By an ingenious arrangement of plates a negative is made, as it were, for each eye and the resulting skiagraph appears as if the observer were looking directly at the object under examination.

CHICAGO.

Bright's Disease in Chicago.—The first death from this disease, according to the weekly bulletin of the Health Department, was recorded in May, 1864, but it was not until 1868 that deaths from the malady were reported in sufficient number to compute rates. In the Annual Report of the Commissioner for 1894 it was shown that the rate had increased 84 per cent. in twenty years, that it is in the decade 1885-1894, compared with that of the decade 1868-1877, and it was then said—speaking of the group of steadily increasing diseases—that: "Sanitarium administration can do little with these diseases or with the increase of Bright's disease and of diseases of the nervous system. The high tension of modern life—nowhere higher than here in Chicago—with its besetting temptations to irregular habits and to excesses of various kinds, and its great strain upon the most complex and most important mechanism of life—is something that the sanitarium can but recognize and regret; its relief and remedy will come only through saner views and modes of life." "Saner views and modes of life" have not yet arrived, and the death rate of Bright's disease has increased upward of another 80 per cent. in less than a decade— that is, from five in the 10,000 of population in 1894 to 9.09 in 1903, or 81.8 per cent. in nine years. The apostle of "The Simple Life" has not arrived in this country any too soon. Chicago needs him.

Smallpox.—Three cases of this disease were admitted to the Isolation Hospital during the week. Of these one was an unvaccinated adult, one a schoolboy ten years of age, who had been admitted on a false certificate of successful vaccination, and the third a baby of ten months not yet vaccinated. Attention is again called to the large number of smallpox cases occurring in infants and children under the school age during the first nine months of this year, as well as during 1903. The plea is renewed for the protection of children against smallpox by means of vaccination during the first year of life. In fact, the best time to vaccinate the infants is during the third month, at a time when the arms are not much used, and before the disorders attending teething have begun.

Fined $100.—A Dr. Maharg, said to be formerly City Chemist, was recently arrested, together with four women, who, garbed as Sisters of Charity, secured contributions for an alleged home for consumptives claimed to be operated by the Doctor at an empty building on North Clark Street, called the Nazarene Mission. He was fined $100, and the women were remanded.

Chicago Medical Society.—At a meeting held October 5, Dr. Hugh T. Patrick showed a case of idiopathic muscular atrophy, the patient being a young woman, twenty years of age, whose trouble began at the age of twelve. She had never been able to close her eyes tightly. She had never been able to whistle or pucker the lips normally. There was marked lordosis. At the age of twelve she was noticed to walk in a peculiar manner, with the shoulders thrown back. The muscles about the arms and shoulders were very weak, and although the deltoids were large and hard, they were weak. There was more or less weakness of the scapula owing to paralysis of the serratus. The case corresponded with the Landouzy-Dejerine facio-scapulo-humeral type. The patient had an affection of the gluteal muscles, and of the psoas and iliacus, whereas the muscles in the lower limbs were good. She could not raise her toes so as to stand on the heels. The case was atypical in distribution, in that it partook of many of the different types. The knee-jerks had almost entirely disappeared when she was admitted to the hospital, but under large doses of strychnine they became distinct, so that now they were normal. Dr. Patrick showed next a case of multiple neuritis, which manifested several interesting features. A third case was one of acroparesthesia nocturna in a young woman, twenty-three of age, who had had this trouble for two years. She was not troubled during the day. In the night she would awake with numbness and tingling which was so intense as to almost amount to pain. The attacks began in the right arm, paralyzing it for the time being, but after getting out of bed, rubbing the arm, putting it in hot water, shaking it, etc., the tingling disappeared, after which she would go back to bed. As a rule, she got this tingling only once in the night. The next case was one of cervical rib. He said cervical rib was not frequent, and most of the cases of cervical rib had been discovered accidentally, either post-mortem or during an examination for other trouble. He showed other cases of muscular atrophy and of multiple neuritis. His last case was one of Caisson disease. The patient could not use his leg below the knee. Patient worked in a caisson, seventy-five feet below the surface, in which the pressure was twenty-five pounds to the square inch. He felt no inconvenience from working aside from pressure in the ears. After working in a caisson for some time, he began to feel tingling and numbness in his legs, so that they eventually became useless. He felt this tingling in his arm also, lost consciousness, and was unconscious the first night after the attack. The next morning his legs were paralyzed. He felt dazed and confused. His arms were all right the next morning, but his legs were completely paralyzed. The speaker said that this disease could be avoided if proper precautions were taken.

Dr. Charles L. Mix reported a case of "Traumatic Neurosis associated with Tabes" in a negro. He said that the cases were unusual. Clinicians of large experience had described but very few cases. In this case the tabes was clearly traceable to specific infection, but the patient's neurosis was caused by a railroad accident.

CANADA.

Impressed with the Cure for Tuberculosis.—Dr. A. de Martigny has returned to Montreal from Paris, and states that he believes that Dr. Marmoreck's serum will accomplish for tuberculosis what Jenner's vaccine did for smallpox. Dr. Martigny went to Paris as a special commissioner for the Montreal Board of Health to investigate the new serum. He will present his report to the Board of Health at its next meeting.

Hospital Saturday in Vancouver, B. C.—Saturday, October 15, was "Hospital Saturday" in Vancouver, B. C. This is now an annual fixture in the life of this thriving, growing city of the Pacific Province. The citizens of Vancouver contribute on this day to the funds of the Vancouver General Hospital, and the Woman's Auxiliary of the institution make a special collection of the boxes which are exhibited in prominent places all over the city. Last year some $1,200 was collected in this manner.

Typhoid Notification in Ontario.—The Ontario Board of Health has issued a special circular signed by the Secretary thereof, Dr. C. A. Hodgetts, calling for the immediate notification to the local boards of health of each and every case of typhoid fever coming under professional care. The Public Health Act required both the householder and the physician in charge of a case of typhoid fever to notify the authorities within twenty-four hours, and it is the intention of the Board of Health to see that the Act is complied with in the future.

Canadian Nurses' Association.—The annual meeting of the Canadian Nurses' Association was held in Montreal recently. The reports for the year of the Registrar, Secretary and Treasurer, were most encouraging. During the year the association had 1,136 registrations and arranged for 1,090 cases. The past has been the largest year's work since the inception of the association in 1895, and it now numbers 200 members. A course of six lectures are arranged for each season given by leading medical men of Montreal.

GENERAL.

Lecture to Panama Natives on the Prevention of Malaria.—Dr. Roland Ross, a retired surgeon of the British Army, who has spent a week in Panama studying the general sanitary conditions, delivered an interesting lecture at Ancon Hospital, in the canal zone, on the mosquito theory regarding malarial fever. He impressed upon his audience the fact that malaria is practically preventable, as was proved in Suez and Cuba, if the general public and the authorities cooperate effectively.

Diphtheria in Trenton.—There is an epidemic of diphtheria in Trenton, N. J., and the health authorities say it will be difficult to check it because of their stock of impure or inert antitoxin. An effort was made last winter to pass an act to establish a State laboratory for the manufacture of pure antitoxin of the standard quality and strength. It was defeated because a couple of bills got mixed up in the not very clear minds of the legislators, and the law that was finally put upon the statute book provides that any Board of Health may contract with some responsible manufacturer to supply antitoxin, free of charge, upon the certificate of an attending physician, to such indigent patients as may require it. From the reported conditions in Trenton it may be judged that responsible manufacturers are not so easily found as might be imagined. It would be infinitely better to have the State supply good antitoxin in all quantities needed rather than have one or more cities stricken with diphtheria.

Government Needs Hospitals.—Surgeon General Rixey, chief of the Bureau of Medicine and Surgery of the Navy, has rendered his annual report to Secretary Morton, showing that the medical corps is in excellent and efficient condition, although the Surgeon General calls attention to the many difficulties under which it labors. It is stated that the future needs of the service will require hospitals at Charleston, S. C.; Guantanamo, Cuba, and Olongapo, P. I. The failure of the navy medical service to obtain good and ambitious surgeons is attributed in part to the fact that assistant surgeons receive fifteen per cent. less pay when on shore than do passed surgeons in the army. The naval hospital corps is reported to be in excellent condition, and it is recommended that it should be recruited to a strength of 1,000. It is also recommended that the number of pharmacists in the medical corps be increased to fifty. As was to be expected as a result of the President's orders muzzling those who might talk about estimates, none are given out for publication in detail in connection with this report. The estimates for medical services are, however, greater than last year.

Sensible Animal Philanthropy.—The late M. Léon Clery, for many years a prominent member of the Paris bar, made a will which shows that his well-known love of animals had a strictly practical side. He has left an annuity of £120 per annum for the master or mistress of a primary school in France or Algeria who best fulfils the conditions of a program which includes teaching children the difference between useful and harmful animals, instructing them to respect harmless snakes, toads, owls, etc., which old prejudices have caused to be the object of antipathy, and teaching children the utility of these animals. These prejudices, we regret to record, have too frequently been observed in the most zealous advocates of the Society for the Prevention of Cruelty to Animals, particularly in those specially drawn toward the antivivisection propaganda. The prize is to be awarded annually by a committee chosen from among the members of the Society for the Prevention of Cruelty to Animals. M. Cléry has also made several interesting bequests to the Paris museums; and at the end of his will he expresses a hope that the legacies in money will not be wasted by heavy legal expenses.

Military Surgeons' Congress.—At the concluding meeting of the International Congress of Military Surgeons held at St. Louis last week, officers were chosen for the coming year. Surgeon-General Walter Wyman of Washington, D. C., formerly first vice-president of the association, was chosen president; Major Albert H. Briggs of Buffalo, vice-president; Brig.-Gen. Robert M. O'Reilly, of Washington, D. C., of the United States Army, second vice-president; Major James Evelyn Milcher, of Carlisle, Pa., belonging to the United States Volunteer Service, secretary, and Major Herbert A. Arnold, of Ardmore, Pa., attached to the National Guard of Pennsylvania, treasurer. The winners of the Enno Sanders prize essay contest were announced. The first prize was awarded to Lieut.-Col. William Hill-Clime, of London, England, for the best paper on military surgery. The prize consisted of a lump of gold worth $100, on one side of which appeared the effigy of Enno Sanders of St. Louis, the giver, and on the reverse side the line, "For the best paper on military surgery." The second prize was awarded to Lieut.-Col. Hathaway, of the Royal Volunteer Medical Corps of Ihause, India. The prize was a life membership in the Association, estimated at $50. The meeting place next year will be Detroit, Mich.

The Canteen.—This subject will not down. So long as the Army officers are confronted by a condition and not a theory, the practical solution of the problems of drunkenness and of venereal diseases is to be found not in misty vaporings, but in sound common sense. Since Gen. Corbin's report showed that that very experienced and capable observer thought the time ripe for advocating the restoration of the army canteen, testimonies in the same direction are multiplying, writes the *Times*. The Judge Advocate-General of the army appends to his annual report the reports of two of his subordinates, the Judge Advocate of the Department of Colorado, and the Judge Advocate of the Department of Texas. Each of them emphasizes the evil effects upon the army of the abolition of the canteen, as promoting crime in the army, including the crime of desertion. The abolition, according to Col. Dunn, has resulted in multiplying "saloons and brothels," according to Col. Roberts, in multiplying "the saloons and dives that the virtual abolition of the canteen feature of the post exchange has made a universal feature of every military post." And Gen. Barry, the Commander of the Department of the Gulf, in his annual report, remarks: "It would add much to the discipline and contentment of the enlisted men at these outlying stations were the post exchange fully established, with the privilege of selling beer and light wines." The testimony of the officers of the army as to the evils of abolishing the canteen is virtually unanimous. It is they who have the greatest interest in the efficiency of the army, to which temperance is of course essential. They are the only expert witnesses. If one asks why, then, does not Congress authorize what all the experts agree to be so desirable, the only answer is that Congress goes in fear of a number of misguided persons who know nothing about the matter, and who have no right to an opinion upon it. If these people would kindly mind their own business, and refrain from trying to impose their ignorant views of the subject upon the lawmaking body, the canteen would be restored without opposition, save from those busybody women, of both sexes, who are afflicted with the mania to reform—someone else.

Panama Health Situation.—At the present time the health conditions are, relatively speaking, good. Panama is more healthful than other low coast places in the tropics hereabouts. The average number of deaths in Panama now is 100 a month. Last month 101 deaths were recorded, and the preceding month 97. Taking the population as 20,000, the ratio is easily arrived at. Sixty per cent. of the deaths occurred among the natives, the remaining 40 per cent. being divided among Europeans, North, Central and South Americans, and the other foreigners. The mortality among the North Americans was slight. Owing to the very unsanitary manner in which the natives live, especially the lower classes, it is remarkable that the death rate among them is not higher. Tuberculosis is a very common disease with them. Last month there was nineteen deaths from that disease alone, more than from any other disease. There have been a few cases of yellow fever this year, and there are at present two or three patients in the canal hospital, Italians, now on the road to recovery. Only one death from yellow fever among the Americans has occurred, the victim being Cunningham, an employee in the police service of the canal. The Americans in general have retained exceptionally good health, notwithstanding the fact that they have come down during the unhealthful season. Most energetic measures have been taken by the United States sanitary service to stamp out this disease, and while, owing to the close proximity of yellow fever districts, it may not be stamped out altogether, yet there is no doubt that it will be reduced to a minimum. Guayaquil, a well-known yellow fever hotbed, is only three days from Panama by steamer; hence, since the incubation period is fixed at a maximum of ten days, a person contracting the disease in Guayaquil can take passage for Panama and be in Panama a few days before the development of the disease. The sanitary officers are waging an incessant warfare on the mosquitoes, and are gradually getting all the canal buildings screened. Particular care is taken to screen all patients. Among the other diseases prevailing are to be enumeraed smallpox, leprosy, beriberi, diphtheria, malarial and pernicious fevers, and occasionally pneumonia. There are some cases of leprosy, particularly on the island of Taboga, about fourteen miles distant from Panama. The lepers run at large. Beriberi has been common among laborers, and in recent years it has numbered victims in the upper classes. The most common disease of all is malaria, and many people, including natives and foreigners, suffer from it. It is not amiss to state, however, that the malaria is in most cases contracted through an utter disregard of all precautionary measures, the vast majority not even taking the precaution to sleep under mosquito netting.

OBITUARY.

Dr. Frank Greenough, formerly one of Boston's most conspicuous physicians, died in Brookline, Mass., October 16. He was born in Boston sixty-seven years ago, and was graduated from Harvard in 1859, and afterward studied at several European medical universities.

Dr. William White, of Abingdon, Va., is dead in a hospital in Baltimore, where he underwent an operation. He was a brother of Judge John P. White, Chief Justice of the Supreme Court of Texas.

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSOCIATION.

Twenty-first Annual Meeting, held at the Academy of Medicine, New York City, October 17, 18, 19 and 20, 1904.

FIRST DAY—TUESDAY, OCTOBER 18.

The President, William Harvey Thornton, M.D., of Buffalo, in the Chair.

Conservatism versus Early Intervention in Simple Dystocia.—Dr. William J. Meyer, of White Plains, N. Y., read this paper. He said that although much might be said concerning the unusual conditions which the obstetrician encounters, such as fetal monstrosities and abnormal conditions in the parturient woman, other than those to which he referred later on, he wished to emphasize the importance of active intervention in a certain class of cases which, too frequently, are neglected, although very frequently met with. These cases were those in which dystocia resulted from a lack of expelling force or from resistance encountered in the birth canal of an anatomically normal woman. There is generally an unwholesome fear of assisting labor. This, he said, was due largely to the fact that our predecessors had established a precedent from which we were loath to depart. The parturing woman cannot control the expelling force of her uterus, and often the life of the child is endangered by waiting too long for the descending head to dilate a rigid and undilated os. The obstetrician, having fully acquainted himself with conditions, should not fear to intervene to help in the dila-

tation of the undilated os. Dr. Meyer said that he knew of no physiological reason for not using the forceps early in very many cases, and that he had not found that the proper use of forceps had produced laceration. In 186 consecutive cases he had produced no laceration, and had no subinvolution nor post-partum hemorrhage He said that he had found the tent useless in producing dilatation of the rigid os and that the Barnes bag afforded little help, but that manual dilatation was always to be commended. This, he said, required considerable physical strength, but that, when the laws of labor were thoroughly understood and observed, the results justified this form of intervention and also the early use of forceps. He had followed this plan for five years, and he believed that he had not only saved the lives of many infants but had lessened the strain upon the strength of the mothers. He reviewed the histories of two cases as examples of this. In one of these, to which he had been called in consultation, the mother had been in violent fruitless labor for fourteen hours. Manual dilatation of the rigid os and the use of forceps had been forbidden when he first advised this procedure. At this time the infant was vigorous, the heart sounds being clearly distinguishable. Several hours later, when the labor pains had continued for fourteen hours in all, he had dilated the os and removed the dead infant with forceps. One year later he attended the same woman and found her os uteri contracted and the uterus vainly trying to expel its contents. At this time, however, being alone in charge of the case, he had dilated manually the os and had delivered a healthy living child. The second case was similar in that the os was rigid and uninfluenced by forcible labor pains, although these had occurred at fifteen-minute intervals for two hours. After twenty minutes' manual dilatation he had delivered the child alive, although a previous similar condition had resulted in a stillbirth. In conclusion, Dr. Meyer said that stupid conservatism was the cause of many deaths, and that if manual dilatation and the early use of forceps were more frequently resorted to, the fear of maternity, so common among women, would be greatly lessened.

Manual Dilatation.—Dr. E. D. Ferguson, of Troy, N. Y., said, in the discussion which followed that he fully agreed in the use of manual dilatation, and that no one could judge accurately the amount of force applied to the os when instruments were used for this purpose. Manual dilatation, on the other hand, was always subject to the exercise of judgment. The reason for applying artificial dilatation was to be found in the attempt to equalize the extensive forces and the resisting forces. But keen judgment should be used, he said, and it should not be forgotten that meddlesome midwifery is bad midwifery. He further emphasized the value of manual intervention as compared with instrumentation, by referring to those cases in which embryotomy becomes necessary. The embryotome is a dangerous instrument, and might do serious injury in the uterine cavity, while the use of the hand of the obstetrician is always a safe method of emptying the uterus.

Dr. Bernard Cohen, of Buffalo, said that one advantage of using the fingers to dilate a rigid os is that the cause of the rigidity was often distinguishable. Another was that the membranes may be preserved, which is not always possible when other measures were employed. The fingers, having partly dilated the os, may often be withdrawn, for they act as a stimulus to the uterus when that organ is not contracting vigorously. This was particularly true when quinine and morphine had been administered. Dr. Cohen said, however, that he did not consider it wise to interfere before about six hours had elapsed, thus differing from Dr. Meyers. In the use of forceps he preferred to use axis traction to the use of the long forceps more commonly employed. He further said that the exact time at which to use forceps was a nice point, that there was what he termed an "*obstetrical moment*" when they should be applied. In regard to lacerations, he said that he had averaged during an experience of over twenty-five hundred cases covering eight years, one tear in every seven cases, and that of these the proportion of cervical lacerations had been one in five, although he had had one hundred cases recently in which no laceration had occurred.

Complete Dilatation Before Applying the Forceps.—Dr. J. B. Cook said that the obstetrician must be more than a midwife. He must not wait for forty-eight hours, but must assist the laboring mother. He advocated complete dilatation before applying the forceps, or at least the force must be applied until the muscles surrounding the os were paralyzed. This should always be done under either complete anesthesia or without any anesthetization, as partial anesthesia is dangerous under these conditions. It is more dangerous, he said, to wait too long before applying the forceps than to apply them too early, and that the exhausted muscle does not heal readily, after a laceration and, further, that the forceps should be left on until the head is fully delivered, because it it becomes necessary to reapply them a tear almost always follows.

Asthma and Its Relation to Environments.—Dr. George N. Jack, of Buffalo, N. Y., read this paper. He said that asthma is not a disease, but is a symptom. It is, he said, a part of a vicious cycle; an abnormal biochemical and complex pathological process. It originates usually in the intestinal canal through a long-standing indigestion, and toxemia with faulty absorption and metabolism. This produces a toxic or lymphogenous chyle that generates an unstable blood, characterized by its extremely varied numerous and alarming paroxysmal morphological changes. These often alternate between lymphocytosis, an intestinal toxemic leucocytosis or anematosis, accompanied anatomically by a hyperplasia of the lymphatic and glandular structures and clinically by a most agonizing dyspnea. The nerve muscle spasm theory, he said, is now exploded. The anatomical structure of the air tubes disproves this, as they are composed of bone-like rings so constructed that no muscle contained in them could spasmodically contract in any way to interfere with ingress or egress of air. This is true of all the respiratory tract except the vocal muscles, and these never do except in laryngismus stridulus. Asthma, he said, is not a phantom disease produced instantaneously by smells, etc., but is a well-defined pathological process that has been gradually developing for months, years or generations. The asthmatic patient is always loaded for an attack. Lymphocytic and toxic leucocytic asthmatics with their unstable and rapidly disintegrating blood, their enlarged mucous glands and their relaxed blood and lymph capillaries in one class and the anemic asthmatic and his impoverished blood in the other, produce a variety of conditions that individualize each asthmatic and render him susceptible to a certain environment. Some environments explode this pathologically-charged machine into an asthmatic manifestation or encourage it when already exploded; other environments retard the explosion or quell it when it is already in action. As a simple example of this, he called attention to the common occurrence in the histories of all asthmatics, namely, when a bad day may be followed by a comfortable one, this being due to atmospheric conditions frequently. Dust, he further said, acts in causing an asthmatic attack by irritating en-

larged glands, but it is of minor importance, as it is only an aggravator and not a cause. Concerning seasonal changes, he said, that the fact that winter attacks were as frequent as those of other seasons and that his, as well as the occasional occurrence of an attack occurring in midocean, argued against the pollen theory. The fact that, in the asthmatic, the air tubes are the dumping ground of the toxic blood, is the factor in determining the location of the symptoms of the general diseased condition. In the treatment of asthma, Dr. Jack placed out-or-door life, in a high altitude, free from excess of moisture, and having an abundance of sunshine, as of first importance. This, however, should be in connection with attention to improvement in the intestinal disturbances.

An Old Specialty.—This was the title of a paper read by Dr. Jane Lincoln Greely, of Jamestown, N. Y., in which she painted a beautiful word picture of the life of the family physician. As the lymph, a carrier of all that is best for the living cell of the body, is to the animal organism, so is the family medical adviser to the community in which he labors. The special investigator and specialist is necessary for the advancement of the science of medicin, but the general family doctor also has his special field in the application of the results of original investigations. In doing this he wields unusual influence and in his supervision of the families in his charge he is not only the curer of disease but the far-seeing director of the lives, and by his guidance and instruction the general mental and moral as well as physical condition of the members of his community may be greatly influenced. Knowledge, wisdom, conscientiousness, unselfishness, character, must be his.

An Atypical Case of Appendicitis.—Dr. W. B. Reid, of Rome, N. Y., reported this case and said that in searching the writings of Deaver, Fowler, Mynter and Ochsner, he had found no mention of a condition similar to this case and that this stamped it as a rare case. A woman aged forty-nine years, married, had borne one child. Her general health had been very good except chronic indigestion and occasional swelling of the ankles. She had been thrown from a sleigh and fell upon her shoulder. This had been followed by pain in the left hypochondrium and later in the right lumbar region, the abdomen had been disturbed and there was some soreness at McBurney"s point. Later there had been board-like rigidity of the abdominal muscles. The diagnosis had been traumatic appendicitis. In consequence of patient's having glycosuria and albumenuria, she was not operated upon but was put upon starvation treatment. The temperature varied from 102° to 103° F. There was never any pain, although there was swelling the size of an apple in the right iliac region. Later, under local anesthesia an incision was made into the swelling, when a large amount of foul-smelling gas was liberated which caused Dr. Reid to suppose that he had perforated an intestine. When, however, he found pus at the bottom of the abscess cavity and the gangrenous stump of the appendix he concluded that he had a gas-producing infection. The question then arose: What micro-organism was present? He said that the reputation of the colon bacillus for marked variation, both in morphological appearance and biological characteristics, was well known but that the possibilities of an infection by the *Bacillus lactis aerogenes* was one which he had considered. Cultures made from the pus had in general resembled those of the colon bacillus. In summing up, Dr. Reid said: (1) The case was one of long standing appendicitis, as shown by the history of pain in the side and digestive disturbances. (2) The history of traumatism was purely a coincidence. (3) The acute attack was caused by an infection of the *Bacillus coli communis* and followed by abscess formation. (4) The acute nephritis was caused by an infectious toxemia, as a postoperative examination of the urine proved the urine to be free from albumin and casts. (5) Associated diabetic condition which, on examination of the urine showed to still have continued months afterward, furnished a sufficient amount of sugar in the culture media contained in the abscess cavity for the production of gas formation. The question then followed: Was there a double infection of the *Bacillus coli communis* and *Bacillus lactis aerogenes;* or was the infection a single one of the colon bacillus which, under peculiar conditions of diabetic culture media, produced one of the involution forms which resulted in gas formation?

Neophroptosis. Its Gynecological Importance.—This paper was read by Dr. A. H. Goelet, of New York, who said that the prolapse of the kidney has an important bearing upon gynecological conditions and that it is often overlooked as an etiological factor, both in producing and in maintaining congestion of the pelvic organs and diseased conditions coincident thereto, and in producing symptoms which are referred erroneously to the pelvic organs. This he had frequently observed in cases coming to him from other gynecologists. He pointed out that the kidney, when prolapsed, overlaps the ovarian vein, as it ascends along the spine, and compresses this vein, thus obstructing the return circulation from the pelvis when the waist is constricted by corset or clothing. It is not necessary, he said, that the constriction at the waist should be more than sufficient to support the clothing for the intestinal distention always associated with this condition is an important factor in forcing the kidney back against the spine. It might seem that, the kidney being movable, would escape such compression but the colon being attached to the kidney drags upon it when it is distended and holds it in position at the waist line, favorable for compression. The distended bowel must necessarily become displaced below the waist line since there is no room for it above. He said, also, that even in the early stages of prolapse, the kidney may retard the circulation of the ovarian vein, because, when the kidney descends, its lower pole swings inward toward the spine overlapping the vein. Compression and consequent obstruction of circulation of the ovarian vein may be brought about in another manner by a prolapsed kidney. The vein being in front and the ureter behind, where they cross, when the kidney descends the ureter becomes bent upon and drags on the vein. Distention of the ureter from accumulation of urine in consequence of obstruction at the point of flexure will also cause pressure on the ovarian vein. From these statements, he said that it would be seen that prolapse of the kidney is an important element in maintaining congestion of the pelvic organs and is to be regarded as a factor and a very important one in causing diseased conditions arising therefrom. He said, further, that it is certainly true that in most women having prolapse of the kidney there is some associated pelvic disease. The position of the kid-

ney may not always be the sole cause, but he considered it an important etiological factor in these conditions and when it is so, a cure is not possible without fixation of the kidney. This, he said, had been so frequently demonstrated that he was convinced that a prolapsed kidney has a strong influence in causing and maintaining such conditions as persistent leucorrhea, endometritis, uterine hemorrhage, uterine displacements and even ovaritis and salpingitis and hemorrhages into the pelvis, irritable bladder and cystitis. Gynecologists, Dr. Goelet said, should make a special point of recognizing this condition or excluding it in making diagnoses. This should be a matter of routine, to examine all patients for this purpose, not once but repeatedly, if necessary, until they shall be convinced of its presence or absence. Repeated examinations are necessary, he said, because the colon, when distended, is interposed between the kidney and the abdominal wall, acting like an air cushion, making it impossible to distinguish the kidney; therefore, distention of the colon must be dispelled before a satisfactory palpation may be made. The frequency of prolapse of the kidney is another reason for making this examination. In view of the fact that the kidney is an excretory organ and with knowledge that its function is seriously impaired by its prolapsed position, that it is so often disregarded, is a matter of surprise to the surgeon who constantly has opportunities to see good results from the operation for fixation of the prolapsed kidney. It is quite true, he said, that many patients exist for years with kidneys out of place, but they are chronic invalids and their kidneys are diseased, for a prolapsed kidney invariably becomes diseased eventually and chronic inflammation results in the pelvic organs when the return circulation is interfered with. He said that seventy-five per cent. of all patients with prolapsed kidneys have evidences of inflammation in three years, and that if others could see these kidneys as the surgeon does on the operating table, there would be less hesitancy in advising operation for correction and that the operation would be more often successful in affording relief as it might be done more frequently before the kidney had become incurably diseased. He said, in conclusion, that he had performed one hundred and ninety-seven consecutive nephropexies in forty-seven of which he had fixed both kidneys, and had had no deaths. Hence it could not be said to have any mortality rate.

Transillumination of the Stomach.—Dr. Robert Coleman Kemp reviewed the history of this method of diagnosis in diseased conditions in the stomach giving credit to Max Einhorn for first applying it to the living subject. He exhibited Einhorn's instrument and the one devised by Lockwood for this purpose and pointed out the disadvantages of both. He had improved upon the Lockwood instrument by adding to it an accessory cable, by means of which the electric bulb might be drawn up to any part of the stomach which had not been possible with the device as originally used. He had used, in a large series of cases three fluorescent media: (1) Quinine bisulphate, ten grains in a pint of water; (2) esculin; (3) fluorescin and sodium bicarbonate and fluorescin and lime water. The quinine solution became fluorescent only upon the addition of sulphuric acid. No deleterious results had occurred in his cases. He emphasized the importance of studying the motor function of the stomach in connection with transillumination and said that these two procedures offered a more certain means of diagnosis in gastric dilatation, gastroptosis and tumors in the wall of the stomach than any other method. He said further that his experience had shown him that the normal stomach may vary greatly in capacity; in some individuals eight ounces being the normal capacity, while in others two quarts might be contained. As long as the motor and other functions are normal, the abnormal size of the stomach did not render it pathological. When the lesser curvature is in its normal relation to the diaphragm, the lower curve is at the umbilicus and the motor function is insufficient, there is a condition of dilatation. He demonstrated a method for supporting the dilated stomach, using for this purpose a wide strip of adhesive plaster, cut so that when applied, a straight edge extended across the abdomen at the level of the umbilicus, while the lower edge was so cut that an obtuse angle was directly in the middle of the front of the abdomen. This bandage was applied and was then reenforced by two additional strips applied over the first strip and extending around each side. This, he said, was not only a cheaper but a better method of support than the prepared abdominal belts of the dealers. He said, in closing, that, in attempting to outline the stomach by means of distention with air, the intestine was frequently distended also and that it might ride up over the lesser curvature of the stomach and thus disguise the real condition present. This was a difficulty which was of course not met with in the use of transillumination with fluorescent media and the modified Lockwood transilluminator.

A Substitute for Rubber Gloves.—Dr. Frederick H. Wiggin said that in consequence of the frequency of perforation of the rubber glove used by surgeons, a substitute was desirable, and he offered the following as a very satisfactory substitute:

℞ Ether ..... ℥ xlix
Alcohol (96 per cent.) ..... ℥ xlix
Celloidin ..... ℥ i
Castor oil ..... ℥ ss

This, he said, when applied to the hands soon hardened and furnished protection equal to that of rubber gloves, was flexible and was not easily injured. It was, he said, not soluble in water or ordinary alcohol, but that it could be easily removed by strong alcohol and ether, equal parts. Moreover, it was cheaper than rubber gloves.

Salivary Calculi.—Dr. Herman Jarecky, of New York, said that Foster had reported one hundred and six cases of calculi in the salivary glands and ducts, and that forty-seven cases had been reported by other writers, but that while most of these cases had been those in which calculi had been found in Wharton's duct, and some had been cases found in Blandin's ducts, there was no record of a case in which calculi had been found in both of these ducts in the same patient. He reported three cases and exhibited the calculi which he had removed. In one of these cases he had removed stones from both Wharton's duct and Blandin's ducts. The stones, he said, were usually formed upon some nucleus of foreign matter, as toothpick ends or particles of food, and consisted of calcium carbonate or calcium phosphate. They had been removed by the use of local anesthesia, using simultaneously adrenalin, thus making a painless and bloodless operation. The calculi from Wharton's ducts were pear-shaped and those from Blandin's ducts were rod-shaped. He called attention to the importance of considering the possibility of a

salivary calculus in every case in which there was swelling in the submaxillary region. One of his cases had been diagnosed malignant disease, and had been treated accordingly by the X-rays.

Radical Operation for Carcinoma of the Breast.—Dr. Willy Meyer, of New York, described the technic of this operation, as he has developed it. The main points in which it differs from the usual procedure, as proposed by Halstead, are the dissection of the diseased tissues from the clavicle and axilla downward and inward in the direction of the branching of the great vessels, thus making it possible to ligate the main vessels early during the course of the operation; the severing of the tendon of the pectoralis major muscle at the beginning; and the retention of the pectoralis minor muscle, to which the lower skin flap is stitched later. Dr. Meyer said that it has been proved that the pectoralis minor muscle is never involved in the carcinomatous process, therefore it is not necessary to remove it and that it helps, moreover, to fill in the inevitable gap left after removal of the breast. He said, further, that during his ten years' experience with this operation he had had only two deaths, and that neither of these had been due to the operation directly.

Prolonged Fasting in the Treatment of Acute Diseases.—Dr. Norton Jerome Sands, of Port Chester, N. Y., read this paper. He said that during the course of acute diseases the digestive powers are in abeyance in proportion to the severity of the disease and that too frequently the patient is overfed. This, he said, aggravated the condition of the patient by setting up intestinal indigestion with resulting toxemia. During tewnty-one years he has gone to the other extreme by withholding all food during the active stages of the acute diseases, giving only water. He reviewed his treatment of typhoid fever, saying that he withheld all food for twenty-one days, and, after thoroughly cleaning out of the bowel, he gave two quarts of water a day. His experience had shown him that there was no tympanites and no diarrhea, and that the temperature was usualy two or three degress lower than is common in typhoid. He had also found that the cold sponge was not necessary after the first week. After the third week he resumes liquid food, and he further said that contrary to the usual expectation the patient was not weakened by his prolonged fast, and that he even does not seem to be as weak as the patient who is fed in the customary way in typhoid. All other acute intestinal diseases he has treated similarly. Food, he said, is imperfectly digested during the course of all acute intestintal diseases, and that, therefore, feeding is irrational; it only adds to the gastrointestinal disturbance.

Dr. Wiggin, in the discussion, said that he had found that sepsis was a condition in which it was not advisable to feed the patient, and that he thought fasting was valuable in such conditions.

The Acetone Bodies in Diabetes.—Dr. Heinrich Stern, of New York, read a paper on this subject. He said that the problem present was how to cope with the acetonuria without aggravating the diabetes. In diabetes acetone substances are invariably expressive of a state of undernutrition. This may be, he said, occasioned by the one-sided diet which, of necessity, must be pursued in grave cases of diabetes. It will ensue, however, although probably somewhat later when the regimen exhibits abundant albuminous substances and immoderate amounts of carbohydrates. He dismissed the plan of giving oatmeal and butter as not only productive of discontent in the patient, but as not furnishing the required food substances, and advocated the abandonment of every other food and the administering of the yolks of hen's eggs. The rationale of the *yolk cure*, he summed up as follows: (1) Palmitin, stearin and olein the fat substances of the yolk, occasion but small amounts of acetone bodies in the combination in which these fats exist in the yolk, they yield no butyric acid, or hardly any. (2) The large amount of lecithin supplied to the organism by the yolk tends to the restoration of the nerve forces and the amelioration of the cachectic condition. (3) The occurrence in the yolk of a diastatic ferment, assisting in the conversion of amyloid substances introduced by proteids and allowed vegetables. (4) Digestive secretion stimulating function of the yolk. From ten to forty yolks a day, and occasionally a small amount of proteid and non-avoidable carbohydrates, such as green vegetables, may be given, he said. He presented a case illustrating the benefit derived from this treatment, a boy in whom a previous acetonuria and glycosuria had entirely disappeared and who had gained considerably in weight.

Ocular Reflexes—their Influence on the General Health.—Dr. S. W. S. Toms, of Nyack, N. Y., said that conditions resulting from reflex irritation due to eye-strain, were often treated in vain by the general practitioner, and that the patient as a last resort went to the quack for relief. Slight astigmatism, he said, may produce hysterical or even more profound nervous conditions. The symptoms are frequently legion, but that headache, nausea, vertigo, symptomatic cardiac affection, night terrors or local conditions in the eye, such as hordeolum and conjunctivitis, were common. No accurate correction of abnormal conditions may be made without the use of a mydriatic, and he cited numerous cases in which serious general conditions had been removed by the correction of faulty eye conditions. One case of unusual interest was that of a spasmodic tic simulating chorea which had been removed by the correction of an exophoria.

An Epidemic of Mild Smallpox.—Dr. Edward Munson, of Medina, N. Y., reviewed an outbreak of what had been diagnosed at first as chickenpox, but which had been proved later to be true smallpox. Many of the cases were so slight that the patients had not even been confined to their houses. In connection with this he proposed, as a posible cause of the mildness of the disease, inherited immunity due to long-continued vaccination among the ancestors of the patients together with the modern hygienic conditions.

(To be Continued.)

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirtieth Annual Meeting, held at Cincinnati, Ohio, October 11, 12 and 13, 1904.

The President, Hugh T. Patrick, M.D., of Chicago, in the Chair.

Prayer was offered by Rev. Chas. Frederick Goss, after which the Mayor of Cincinnati delivered an Address of Welcome, which was responded to by Dr. Dudley S. Reynolds, of Louisville.

The Scientific work was divided into two sections, Medical and Surgical.

PROCEEDINGS OF MEDICAL SECTION.

What Shall be Done with the Criminal Insane?—Dr. John Punton, of Kansas City, Mo., in a paper with this title, said that the conflict of authorities raging between law and medicine was responsible for much miscarriage of justice. A mutual conference to adjust differences of opinion and formulate conclusions relative to the medicolegal aspects of insanity in keeping with the more advanced state of medical knowledge, which

could be used as a criterion in courts of law, was greatly to be desired. The skilful manipulation of law, as now applied, often swept aside the entire medical aspect, even when guilt was admitted, and gross errors of justice resulted. The members of the American Psychological Association and the general medical profession were appealed to for their assistance in defining the mental condition which should exonerate a criminal from punishment. The wide difference of opinions prevalent in the public and professional minds relative to what constituted criminal responsibility of the insane rendered a concensus of medical opinion a necessity. Very few of the insane were wholly irresponsible for their misdeeds, and they should, therefore, incur, with certain restrictions, some form of punishment. In view of the degrees of responsibility associated with insanity, the just and equal disposition of the criminal insane became a question of the highest importance. The prevalent horror and disgust at the punishment of an insane person for criminal misconduct was a fallacy which should be condemned, as it often proved to be the responsible agent for the plea of immunity from punishment by murderers on the ground of insanity. The declaration of the law that the insane man was wholly irresponsible was a gross confession of weakness. Some courts recognized modified responsibility and instructed the jury to commit the insane criminal, if found guilty, to the State Insane Hospital until his recovery, when he shall again be set free, and this usually happened a very short time after punishment. The just or humane medical disposition of the criminally insane would seem to demand his incarceration in a special institution under medical surveillance and subject to certain restrictions suited to each case, and he should never be allowed to associate with innocent inmates of the State Hospital. A concensus of medical opinion on the vital important question above stated would tend to harmonize the present misunderstanding between law and medicine, and would thus aid in a more just and equitable disposition of the criminal insane.

Dr. A. Ravogli, of Cincinnati, in the discussion, deprecated the tendency to generalize too much in discussing the criminal insane. He reported a case in which an epileptic committed several murders before his insanity was recognized.

Dr. Charles W. Hitchcock, of Detroit, said this was a very delicate question for the medical profession to decide, and a case was reported, showing that justice might miscarry, even where there was an institution provided for the incarceration of those not responsible under the law.

Dr. G. Frank Lydston, of Chicago, disagreed with the previous speaker that this was a delicate question for the medical profession, and said that the entire subject of criminology should be relegated to the medical profession, so far as the physical conditions and remedies therefor were concerned. Many irresponsible individuals were punished. Punishment for crime had proven a distinct failure. Both sane and the insane criminals should be removed from our social system and isolated. The principal should be not punishment, but simply social self-defense. What should we do in regard to the propagation of the criminal insane? We had not yet come to the sterilization of these individuals, but undoubtedly would do so.

Dr. F. W. Langdon, of Cincinnati, said that, if the profession was given full power in this matter, it was questionable whether it would be able to draw the lines satisfactorily. The legal and medical professions had different points of view, and therefore their conclusions must vary. He agreed with Lydston as to the punishment of the sane and insane. The physician should not arrogate to himself the fixing of the penalty that probably was never right.

Dr. B. F. Beebe, of Cincinnati, stated that the law had been coming to medicine on this question, because the prosecutors had been securing the assistance of medical men. Society must be protected, but the question was how and when and where to take care of the criminal insane. We must determine what constitutes responsibility or irresponsibility. While the laws of the various States did not agree, there was practical unanimity among those who had studied this subject from a medical standpoint.

Dr. Dudley S. Reynolds, of Louisville, spoke of the qualifications of the jury, requiring that they be not familiar with the facts and were not opposed to capital punishment. Such qualifications did not require that the jury be really competent to decide cases, and medical men were called in to testify as to the responsibility or irresponsibility of the defendant. Medical testimony was based not on an examination of the individual, as a rule, but upon hypothetical questions constructed by the legal gentlemen. The chief trouble was with the legislative conditions in the various States. Any person convicted of a felony should be unsexed rather than killed. No person in his right mind would commit a felony.

Dr. Sprague referred to the fact that the use of the asylum for the criminal insane was being rapidly extended throughout the country by the legal and medical professions. Often the attorneys for the prosecution and defense agreed to rest the matter of commitment or trial with the medical commission of such an institution. Such a reference would be more frequent if there were more assurance that such a medical commission was composed of really expert medical men.

Dr. Hitchcock, in explanation, stated that he did not regard this an indelicate question for physicians, but it was a very delicate question.

Dr. Lydston, in answer to a question, stated that sterilization could be effected by obliteration of the Fallopian tubes in the female, and by obliteration of the vas deferens in the male, without any effect upon the individual, save the arrest of the function of procreation.

Dr. Punton, in closing, said it was desirable to become able to have the court properly instruct the jury in these cases.

Loss of Consciousness and Automatism in Inebriety.—Dr. Thomas D. Crothers, of Hartford, Conn., said that the claims of no recollection or consciousness of events by inebriates indicated a paralysis of certain brain sections during which the victim might act automatically and be without consciousness of the real conditions. Histories of prominent cases confirmed this fact. Many startling crimes were committed in this condition. This was a new phase of irresponsibility which had not been recognized by the courts and only recently had been studied by physicians. The defense of no recollection might be a reality in some cases, and should be recognized by physicians.

Dr. B. F. Beebe, in the discussion, stated that the essential point was to prove the fact of the unconsciousness and the automatism. An idea could not exist if the brain cell was not in a condition to receive and retain an image. Whether unconsciousness was produced by alcohol or any other poison, the result was the same.

Dr. John Punton said that the medical profession ought to know the effects of alcohol upon the nerve

cells, but when this question came up in court there were as many opinions as there were doctors. It was not the individual's opinion the court asked for, but rather what definite knowledge there was and the consensus of opinion of the medical profession in reference to the question at issue.

Dr. Hugh T. Patrick said it was necessary to make a very fine distinction between alcoholic automatism and automatism in the alcoholic. In many degenerates or imperfects, there was a tendency to drink too much. The automatism and the drinking might be the result of a preexisting condition.

Dr. Crothers, in closing, stated his belief that individuals, such as he had described, should be regarded as insane.

General Streptococcus Infection of Intestinal Origin with Report of a Fatal Case.—Dr. G. W. McCaskey, of Fort Wayne, Ind., read a paper on this subject, in which he said that there were constantly in the respiratory, genito-urinary and digestive tracts large numbers of pathogenic germs, which might exist in any one of three states: (1) Actively virulent; (2) innocuous, but with conservation of virulence; (3) as a pure saprophyte. These pathogenic germs, which included streptococci, straphylococci, the colon bacillus, and many others might be transformed from the saprophytic to the virulent state by local or general morbid condition. In the case reported, a girl, aged twenty years, a severe chilling of the surface led to a general infection by the *Streptococcus pyogenes*, which apparently had its origin from the intestinal contents which were almost a pure culture of this organism. No other possible source of infection could be determined. The author drew the following conclusions: (1) The digestive tract frequently contains the *Streptococcus pyogenes* and other pyogenic or otherwise highly pathogenic organisms either in an actively virulent or asprophytic state. (2) These organisms under certain favorable conditions might become enormously prolific with reestablishment or great increase of virulence. (3) Under such conditions the various toxins which these organisms produced are absorbed more or less freely from the intestinal tract, producing a more or less severe toxemia which disappears upon removal of the cause. (4) With local morbid alterations in the intestinal mucosa, these organisms may pass the intestinal wall in sufficient numbers and with sufficient virulence to produce a general infection of a serious or even fatal type. (5) The same result may follow functional disturbances caused by errors of diet, etc., leading to blood stasis and increased diapadesis.

Hereditary Predisposition in Tuberculosis.—Dr. Charles L. Mix, of Chicago, said that hereditary predisposition was usually defined as a specific predisposition toward tuberculosis. The nature of such predisposition was purely speculative. It was really a relic of the humoral pathologists, and existed today because of the difficulty of demonstrating actual infection. The argument in favor of hereditary predisposition was as follows: Tubercle bacilli were ubiquitous; every one was constantly breathing them in. Half of the people became tuberculous; half escaped. Half were, therefore, predisposed, and half were immunes. The major premise was false, as shown by a table illustrating the number of individuals to each consumptive. The table explained the maximum incidence of tuberculosis at the ages of from twenty to thirty-five years. There were many fallacies in the usual statistics tending to support the theory of hereditary predisposition. The reports of the numerous joint investigation committees proved nothing. The interpretation of the family cases of tuberculosis was often faulty; family cases showed infection just as much as hereditary predisposition. Hereditary predisposition implied hereditary immunity, but the latter apparently had no existence. The conclusion was reached that there was no such thing as specific hereditary predisposition.

Dr. G. W. McCaskey, in the discussion, agreed with the author that there was no such thing as a specific hereditary predisposition to tuberculosis. The important thing to remember was that tuberculosis was always an infection, and that no one could ever contract the disease unless infected. There was little doubt that every one living in a civilized community inhaled tubercle bacilli at one time or another, and with more or less frequency, the inoculations proving effective or otherwise, according to the local and constitutional states of the individual.

Dr. A. P. Buchman, of Fort Wayne, said that one did not invariably become tuberculous upon exposure to the tubercle bacillus; otherwise every one would be tuberculous. Often tubercle bacilli might be found in the absence of manifest tubercule infection.

Dr. Mix, in closing, said acquired predisposition existed, and the individual might also inherit a predisposition, not only to tuberculosis, but to any of the infections. There was no specific predisposition to tuberculosis, nor any other infection.

Treatment of Tuberculous Pleuritis.—Dr. James A. Burroughs, Asheville, N. C., referred to the use of intrapleural injections of nitrogen gas, and reported some cases in which he injected the pleural cavity with salt solution for the control of pulmonary hemorrhage in tuberculosis.

Dr. N. McKitterick, Burlington, Iowa, in the discussion, said that injections into the pleural cavity in the presence of diseased lungs and pleura, to compress the lung, was positively dangerous. The method did not merit much consideration in the statistics given by the essayist.

Dr. Carl Von Ruck, of Asheville, agreed with the previous speaker as to the dangers of pleural injection. In tuberculosis of the lungs, the cavities tended to work toward the pleural surface of the lung. To prevent rupture, nature caused a thickening of the pleural surface of the lung at that point. The injection of air or fluid into the pleural cavity to bring about the control of pulmonary hemorrhage through pressure required the breaking-up of the adhesions which nature had formed, in order to accomplish compression of the lung.

Dr. Burroughs, in closing, declared that the matter was still in an experimental stage.

The Obstetrical Significance of the Transverse Diameter of the Pelvis.—Dr. Joseph B. DeLee, Chicago, in a paper with this title enumerated the various kinds of pelves, aside from spondylolisthetic and kyphotic pelves, in which there was a diminished transverse diameter. These were especially the funnel-shaped, the assimilation, the masculine and the infantile pelves. Various methods had been employed in making the diagnosis of lessened transverse diameter of the pelvis. The essayist presented an instrument for measuring the diameter of the pelvis. He believed the transverse diameter was not

infrequently reduced. In such cases there was frequently difficulty in delivery, especially in the passage of the shoulders and the extraction of the aftercoming head. In treatment, the expectant method should not be tried too long. Frequently the forceps sufficed to effect delivery. Not infrequently symphyseotomy might be indicated. In breech cases delivery might often be facilitated by the application of forceps to the aftercoming head. Illustrative cases were reported.

Dr. Henry F. Lewis, of Chicago, said the contraction of the transverse diameter of the pelvic outlet was probably more frequent than was generally supposed. In these cases one should not delay the use of the forceps, which should be applied early. In cases of infection in the male type of pelvis, when the head had well advanced, if the forceps failed, symphysectomy was often an ideal operation.

Dr. DeLee, in closing, stated that in a breech case one was formerly instructed to put the forceps in the pocket. In such cases, one would now put the forceps on to boil. As a matter of fact, the forceps would fit the aftercoming head better than when the head presented. The exaggerated lithotomy position was sometimes of value. He reported a case in which an assistant performed tracheotomy on the child in a breech case. The child lived.

Hydrotherapy in Nervous Diseases.—Dr. Charles W. Hitchcock, of Detroit, Mich., described the effects of hydriatic applications, and showed that water might be made a promoter of elimination and a stimulant to all the vegetative processes. Properly applied, it was a powerful tonic. It might be an excitant, but it was also the finest sedative at our command. The author presented the practical advantages of the use of water in the treatment of neural and psychical cases.

The Treatment of the Morphine Habit.—Dr. Curran Pope, of Louisville, Ky., in a paper with this title, pointed out the peculiar state of mind of these patients and the necessity of appreciating it. A sympathetic understanding of the needs would facilitate treatment. Too much importance could not be attached to the condition of the excretory organs. Preliminary examinations were imperative in each case. There should be thorough and complete elimination before commencing the reduction of the drug, after which reduction might be painlessly carried to a certain point, and all shock avoided. All this time help should be given, not as a substitute, but in the shape of a neurocardiovascular support. When the drug was entirely removed, a substitute should be used, not hyoscine. The value of the nonmedicinal treatment, such as massage, vibration, electricity, hydrotherapy, isolation and moral control, could not be overestimated in these cases. The value of after-treatment and the need of keeping in touch with the patients were a part of the system. Personality also entered a great deal into the question.

Dr. Frank P. Norbury, of Jacksonville, Ill., in the discussion, said he had not always had idealistic experience in the treatment of these cases. Recovery was not always smooth, and relapses were not infrequent. It was advisable to place these patients at rest in bed at once, and after perhaps two weeks the drug might be withdrawn. Often sodium bromide was useful as a substitute for the morphine, and cannabis indica was frequently of value as a stimulant. He reported a case in which the patient used heroin instead of morphine.

Dr. John Punton said the patient must be given to understand at the start that the physician should have his cooperation. The idiosyncrasies of patients to the drug differed, hence it was necessary to treat the patient. Hyoscine was a most valuable drug when properly used, but it was very dangerous when used promiscuously. The majority of physicians who came for treatment claimed they could not spend the time that was regarded as necessary to effect a cure.

Dr. Albert E. Sterne, of Indianapolis, agreed with the essayist in general, but did not think he laid sufficient stress on the reduction of the basis upon which the drug habit rested. One must take into account the fundamental nerve weakness. Even the physically strong might present nerve weakness. Habituation was not purely functional. There was a structural change in the nervous system, which supplied the physical basis for the condition. The use of drugs was to be deprecated. Many of the so-called abstinent symptoms were really not such symptoms. Often hyperacidity required treatment. Furthermore, every morphine habitué was a liar and absolutely untrustworthy concerning his condition.

Dr. T. B. Greenley, of Meadow Lawn, Ky., said that many morphine habitués were able to work and earn sufficient to pay for the drug consumed, and made barely a living, but could not afford to take proper treatment.

Dr. George P. Sprague, of Lexington, Ky., was surprised that the essayist did not begin at once the reduction of the drug, as there was every reason why it should be withdrawn immediately. The patient might be taken off the drug in from five to ten days, except in perhaps one case in twenty. Often the patient was sustained by a minute quantity of morphine. Some patients claimed that one-eighth of a grain was satisfactory, and the reduction to that point was not objected to by them. Often it was better not to stop the drug altogether until one had reached a decreased dosage of one-twentieth of a grain or less, until twenty-four hours could be passed without the drug, without unpleasant symptoms.

Dr. R. E. Haughton, of Richmond, Ind., regarded this condition as a practical toxemia affecting the cellular elements of the brain. After deciding upon the withdrawal of the drug, one must secure absolute control of the patient, in order to be successful in treatment. One must sustain the individual and at the same time secure elimination.

Dr. T. D. Crothers said a melancholic fact was the large percentage of the profession that were victims of morphine. The treatment employed must depend upon the individual. Psychotherapeutics and hydrotherapeutics were useful. Nerve rest was important. Drugs should be avoided.

Dr. Falk said that in prison practice he withdrew the drug from patients at once. The use of ergot, and the administration of elixir of chloral and bromide at night, he had found was not followed by any unpleasant results. None of the cases had been cured permanently.

Dr. B. F. Beebe said the removal of the drug in one week or ten days was too short. The patient should be built up as the drug was withdrawn. The medicine must be withdrawn; elimination should be as rapid as possible and the system built up.

Dr. Pope, in closing, insisted upon four to six weeks for the after treatment, because nutrition must be improved. Treatment during convalescence was

important. When the patient stopped treatment, he should be instructed to return at once if there were any unpleasant symptoms.

Effect of Direct and Indirect Violence Upon the Skull and Brain.—Dr. Albert E. Sterne, of Indianapolis, Ind., read a paper on this subject, in which he presented the following summary: "(1) Injuries of the skull and brain may be classed under two heads, those of impact, and those of momentum, either of which may be occasioned either directly or indirectly. (2) Injuries of impact, however extensive, offer a better immediate and remote prognosis, but must be treated with as little delay as possible, and almost always surgically. (3) Injuries of momentum show graver probabilities both in the immediate and remote effects. (4) In injuries of momentum lesions through *contrecoup* are more apt to occur, with extensive damage to brain structures and often without fracture of the skull, or external wound. (5) After trauma to the skull and brain, the immediate necessity is free drainage and avoidance of intracranial pressure. (6) The possibility of fracture should ever be kept in view after injuries to the head, and scalp wounds should, if necessary, be freely enlarged to determine the wisdom of further operative interference. (7) Progressive coma, after momentum injuries, is a strict indication for operation."

A Clinical Study of the Mental Disorders of Adolescence.—Dr. Frank P. Norbury, Jacksonville, Ill., discussed this subject under the following heads: (1) Adolescence presents a physiological study of contrasts revealed in (*a*) normal psychology of this period, (*b*) psychophyical symptomatology, and (*c*) pathological symptomatology. (2) Clinical groupings of symptoms leading to classification of the mental disorders of adolescence; dementia præcox, katatonia, hebephrenia, hysterical excitement, etc. (3) Clinical considerations of prognosis: (*a*) Evolution of mental disorders (*b*) recoveries, complete, partial; (*c*) terminal dementia. (4) Treatment: (*a*) prophylaxis; (*b*) immediate. (5) Conclusions: (*a*) The family physician must recognize early these important mental disorders; he must cooperate with the alienist in treatment; (*b*) prompt and energetic treatment is imperative; (*c*) prognosis should be guarded.

Insanity in Relation to Obstetrics and Gynecology.—Dr. Henry F. Lewis, of Chicago, contributed a paper with this title. He stated that various types of insanity might affect the pregnant or puerperal woman, or the woman suffering from pelvic disorder. There was no true puerperal insanity, however, as such. Normal pregnancy and even normal menstruation were not devoid of certain eccentricities of temper, tastes, appetites, or even morals. Some degree of mental instability must preexist if the eccentricities were to be exaggerated into insanity. The element of heredity was a potent factor, and could be traced in about three-fourths of the cases. Authorities differed as to the estimated frequency of obstetrical insanity. McLeod's figures gave a proportion of one case to 2,000 labors. Clouston found 10 per cent. of insane women at the Edinburgh Asylum were classified as having puerperal psychoses. Lane from observations in the Boston Insane Hospital for the past ten years concluded that insanity associated with childbirth occurred only half as often as insanity among all women of childbearing age. At best, one could only grant to childbearing an exciting causal relation in the production of an outbreak of insanity. The predisposing instability of mind, often largely hereditary, awaited some awakening impulse in an acute physical or psychical disturbance. Such disturbance might be furnished by disorders of the genital organs in the performance of their normal functions. The relation of disease of the female genital organs to mental disease had long been recognized, but the intimacy of sex relation had been the subject of wide differences of opinion. A very large number of insane women were affected with pelvic disease. Evidence from autopsies and gynecological examinations of insane women by a large number of authorities showed the presence of noticeable pelvic disease in about twenty-five per cent. A considerable number of gynecologists had operated upon insane women at asylums for their genital lesions, and had secured a gratifying percentage of cures and instances of improvement. Hobbs, of London, Ont., observed over a thousand insane women and found pelvic disease of sufficient moment to justify operation on account of the pelvic disease itself in 25 per cent. of these women. All his examinations were made under the influence of an anesthetic, and suggestion was thereby eliminated. Ovarian lesions seemed to influence the mental state the most, uterine next, and vaginal the least. Neoplasms were the least prone to cause mental disorder of all the pathological conditions. Judging not alone from the work of Hobbs, it appeared that there was a much larger proportion of pelvic disease among insane women than among sane; that the pelvic disease had at least an exciting causal relation to the mental disease; that successful treatment, operative or otherwise, of the pelvic lesions would promise good results in the treatment of the mental disease. It was pretty generally agreed that some pathological basis must exist to justify operation.

Newer Conceptions of the Management of Bright's Disease.—Dr. Alfred C. Croftan, of Chicago, Ill., considered this diseases as a cardio-vascular disorder of manifold origin, involving primarily the heart and arteries, secondarily those organs chiefly supplied by end arteries, namely, the brain, the retina, and the kidneys. The degeneration of the kidneys was, therefore, a very common and important, but not a determining feature of the disease. Bright's disease in early stages not infrequently occurred without renal involvement. Primary nephritis with the retention of excrementitious bodies might occasionally be a cause of the cardio-vascular changes. This sequence of events, however, was relatively rare. The management of Bright's disease should be directed towards the prevention or removal of factory operative to affect the heart and arteries. The treatment of the nephritis was incidental, but important. The rest cure of the kidneys, diet (dangers of exclusive milk feeding), hygiene and medicinal treatment were discussed on the basis of the above conceptions.

Early Recognition of Important Eye Lesions by the Practitioner.—Dr. George F. Suker, of Akron, Ohio, pointed out the early diagnostic eye lesions in diabetes, chronic nephritis, and locomotor ataxia. Reference was made to the diagnostic conjunctival spot in cases of measles. He spoke of the frequency in mistaking glaucoma for trifacial neuralgia; also the frequency with which simple, chronic glaucoma was confounded with cataract. He emphasized the need of recognizing the eye conditions as a factor in chorea, functional epilepsy, neurasthenia and hysteria. The relation between gastro-intestinal derangements and

certain eye lesions was pointed out, and the need of a thorough ophthalmic examination in the neurotic, chlorotic and patients of this character emphasized.

Value of the X-Ray to the General Practitioner.—Dr. James E. Coleman, of Canton, Ill., stated that, as the practice of medicine was still largely in the hands of the general practitioner, it made it necessary for him to improve to the greatest extent his resources for diagnosing and combatting disease. X-ray apparatus had become a necessary adjunct. In order that it might be satisfactory, it must be first-class. Every general practitioner should have one text-book on X-ray therapy. The mastery of the details and technic was not difficult when studied, but success depended upon a knowledge of anatomy and proper interpretation of the screen and skiagraph. Cases were cited.

Macular Atrophy of the Skin.—Dr. Edward H. Shields, of Cincinnati, said that this rare disease was first described by Jaddason, in 1892. No other case reported. The author presented the following history of a case: Eighteen months ago red macular lesions were found on the legs and thighs, with no subjective symptoms. Some weeks later the patches lost redness, became softer, depressed, and the skin over the diseased area become shriveled: atrophy continued for several weeks, when the atrophic spot became soft and pale. Owing to the marked irritability of the skin, the atropic lesions did not appear very pale immediately after the removal of the clothing, but after half an hour of absolute rest they became quite pale, resembling those of morphine. He stated that treatment was of little value, yet in due course of time the process was arrested.

Why So Many Errors in the Diagnosis of Graves's Disease?—Dr. J. H. Stealy, of Freeport, Ill., emphasized the importance of a correct nomenclature and its bearing on errors of diagnosis. He pointed out the illogical nature of the term exophthalmic goiter as applied to the symptom-complex of Graves's disease, and showed what a remarkably large number of cases of Graves's disease could be found if sought for. He discussed the percentage of symptoms, the diagnostic importance of each, and also the symptomatology.

Echinachea.—Dr. C. S. Chamberlin, of Cincinnati, made a plea for the recognition of echinacea as a valuable therapeutic agent. He gave a brief history and description of the drug, and referred to the suspicion with which the regular profession regarded remedies introduced by irregular practitioners, and their reluctance to investigate their merits. He cited brief reports of case illustrating the therapeutic value of the drug as an alterative and antiseptic, and its range of application.

The following papers were also read: Pseudo-membranous Croup, by Dr. R. E. Carlton, of Latonia, Ky.; Bacteriology and Immunity, What It Is, What It Teaches, What It Does Not Teach, by Dr. R. E. Houghton, of Richmond, Ind., Two Etiological Factors in Pelvic Diseases in Women, Their Prevalence and Prevention, by Dr. J. H. Firestone, of Freeport, Ill.; Prognosis, by Dr. John M. Batten, of Downington, Pa.

(To be Continued.)

Japanese Sanitation in War.—If reports from Tokio and other Japanese base hospitals are to be depended on it would seem that the Japanese have learned the art of preventive medicine much better than any of their contemporaries. Typhoid and malaria are absent and the number of soldiers invalided for medical disease has been less than one per cent. Surgical asepsis is also noticeable in the surgical wards. Few wounded have died of sepsis.

AMERICAN PEDIATRIC SOCIETY.

Sixteenth Annual Meeting at Detroit, Mich., May 30 and 31, and June 1.

FIRST DAY.—MONDAY, MAY 30.

The President, Augustus Caillé, M.D., in the chair.

Intussusception: Cure by Sloughing of the Intussusceptum.—The case of a baby, seven months old, was reported by Dr. Irving M. Snow, of Buffalo. After a duration of sixteen days' illness there were symptoms simulating ileocolitis, and a gangrenous intestine protruded from the anus. Recovery took place after six inches of the intestine which protruded from the sphincter had been taken off. Four similar cases were also reported in abstract by the same speaker.

Influence of Laboratory Feeding and Weight Index of Infants Suffering from Diseases of the Gastro-Intestinal Tract.—Dr. Maynard Ladd, of Boston, had studied the effects of laboratory feeding upon 216 infants with ileocolitis, fermental diarrhea and other diseases of the gastro-intestinal tract. These infants were under treatment of the clinic for periods varying from one to thirty-one weeks, and the average duration of illness was about seventeen days in the acute cases, while some of the chronic ones had continued for several months before coming under observation. The weight increase of each infant was used as an aid in estimating the effects of the method of feeding upon children of varying ages and stages of development. The infant's weight was taken at the beginning and at the end of treatment, and the ratio of this weight to that of the average normal infant obtained, the result being the *weight index*. More than half the cases under consideration had a weight development of only 40 to 70 per cent. of the normal, when they were first placed under observation. The author divided the results of his observations into four groups, as follows: The first group comprises those infants who made complete recovery from the acute gastric and intestinal symptoms, and whose weight index was maintained or augmented while they were being fed on laboratory milk. There were 109 cases in this group, or a little more than one half the entire number. There was a gain of eight per cent. for this entire group, and the greatest average gain per week was 156 grams reckoned from the lowest average gain attained during treatment. The second group included those infants who recovered from their symptoms and gained in weight, yet displayed a loss in weight index. There were fifty-eight cases in this group, and the greatest gain per week from the lowest weight attained was 94 grams. The infants in this group were not as long under treatment as those of the first group, the duration of treatment averaging only 5.9 weeks in comparison with an average of 8.5 weeks of treatment given to the infants in group one. The gain made in this second group was not great enough to keep up the weight indices, so that there was an average loss of 3.4 per cent. The third group is made up of those infants whose weight did not increase to any great extent, although in general they recovered from the acute symptoms, gastric and intestinal, for which they came under treatment. There were thirty-seven children included in this division. Eleven cases did not improve under treatment, and no further history has been obtainable in eight instances, so that there may have been a fatal outcome in some of them. The average loss in weight

in this group from the lowest point attained was 6.5 grams per week, and the loss in weight index 7.2 per cent. The average length of time under treatment was 3.7 weeks. The fourth group consists of the fatal cases, of which there were twelve, so that the average mortality for the whole number of cases under discussion was 5.6 per cent.

Disturbances Caused by the Employment of Large Fat Percentages in Infant Feeding.—It was the opinion of Dr. L. E. Holt, of New York, that very serious disturbances result from the administration of too great a percentage of fat in the milk selected for infant feeding, even by the most experienced physicians and nurses. A very rich milk, with a percentage of fat often reaching five or even 5.5 is often employed in the same manner as an ordinary four per cent. fat milk would be used, so that the formula may reach as high as six per cent. of fat, instead of 3.5 or four as was intended. The speaker reported some cases illustrating the effects of such errors, among which may be noted the sudden and severe character of the illness, enlargement of the liver, convulsions, laryngismus stridulus or tetany, and stools consisting almost of pure fat. There were also nervous symptoms which ceased when the quantity of fat was reduced and returned one week later, as soon as it was increased to the former amount. Another case observed developed slight rickets, evinced by delayed dentition and craniotabes, with convulsions, which returned after an interval of a week when the fat was again increased to almost its original strength. There was also constipation, so that the bowels had to be relieved by magnesia. It was the conclusion of the author that in those cases where there was any disturbance of digestion the best results were obtained by a lower percentage of fat and a greater one of proteids, and this is in a measure true of infant feeding in general.

Dr. Charles C. Kerley, of New York, had not obtained the results noted by the previous speaker and said that he was in the habit of reducing the amount of food administered until the temperature and the stools returned to normal. He then gave a weak formula, with only four or five per cent. of sugar and not more than one half of one per cent. fat. The children under six months old who had come under his observation in the New York Infant Asylum did well on milk containing only about two per cent. of fat, and seemed to be less liable to intestinal derangements.

It was the opinion of Dr. C. Freeman, of New York, that the working out of the weight index was the most striking feature of Dr. Ladd's paper. Concerning the subject of the second paper, it seemed to him that there was often much confusion in the minds of mothers and nurses as to what high fats consist in. Books on infant feeding often recommend cream, and it is added quite regardless of the fact that it may be 40 per cent. centrifugal cream instead of the ordinary 16 per cent. fat.

Dr. J. Lovett Morse, of Boston, called attention to the fact that eczema and ammoniacal urine often resulted from the administration of too much fat.

Dr. B. K. Rachford, of Cincinnati, desired to find out if auto-intoxication was the cause of the nervous symptoms often seen as a result of too much fat feeding.

It was the experience of Dr. L. E. LaFetra, of New York, that infants prematurely born, and weighing from four to six pounds would often increase in weight with greater rapidity than children born at term, and would triple their birth weight at the end of the first year of life.

Dr. J. E. Winters, of New York, was of the opinion that it was often not too much fat in the food, but too much food which caused most of the intestinal disturbances under discussion. Infants were often rendered constipated because they were obliged to take far more food than they could well assimilate.

Dr. Holt thought that in cases of summer diarrheas infants were often kept too long from milk. In those cases where there was acute intoxication milk must be withheld until recovery was almost complete, but where there was simply intestinal indigestion resulting from dysentric organisms it was not so imperative.

Case of Infant Congenital Hypertrophic Stenosis of the Pylorus.—This was reported by Dr. J. Dorning, of New York. A child weighing 8½ pounds was born March 23, 1903. The parents were healthy and labor was natural. The child was fed by the breast exclusively. It vomited after nursing, but the mother said she never noticed mucus in the vomit, that the milk was always returned fluid, and the child seemed to be able to retain water. The bowels moved two or three times a day, the stools being always yellow in color. The child slept very well, and grew tall, but the limbs were always very thin. The case was seen by Dr. Dorning on May 24. The infant was badly nourished, pale and listless, abdomen distended but not tender, soft and tympanitic. In the epigastric region, just to the right of the median line, a small mass was palpable. The child died on June 7, becoming unconscious while nursing and passing away in two hours. At autopsy the stomach was found to be distended, the pylorus hard and thick, and one inch beyond it the duodenum was deeply congested. There was no ulceration of the gastric mucous membrane, although it was pale in color. There was a decided thickening of the stomach wall in the region of the pylorus. Such a condition, the author said, had now been recorded in the literature about sixty times. A study of these records would lead one to conclude that there might be two distinct pathological conditions with clinical manifestations of a similar nature, one of which is surely fatal unless there is possible relief through operation, and another which may be relieved by proper dietetic measures. It is also possible that these are simply gradations of the same morbid condition. A palpable pylorus, intractable vomiting with no apparent cause and progressive wasting are the symptoms of hypertrophic stenosis of the pylorus. The gastric symptoms are often quite prominent in cases of moderate severity yet under dietetic treatment, may improve or even appear to cease entirely, especially in those cases where muscular spasm is a noticeable factor. If there is no bile in the vomitus, an obstruction above the entrance to the common bile duct might seem to be indicated, but if bile is present it does not necessarily exclude the diagnosis of pyloric stenosis. The diagnosis may be established beyond a reasonable question, however, as well as the symptoms before enumerated, if a palpable tumor is present in the pyloric region. As it is sometimes difficult to palpate very minute masses in the upper abdominal region, the use of anesthetics may often aid in disclosing the presence of a thickened pylorus

which could not be found by the palpating finger. If symptoms of pyloric obstruction are present there is always a strong suspicion of hypertrophic stenosis, for congenital pyloric stenosis displays practically the same ones, and other conditions are so rare in infancy that they may be practically ruled out. All cases do not have the immediately fatal termination of the one cited, and such children often live some time with symptoms of dyspepsia, more or less acutely manifest.

Renal Decapsulation as a Cure for Chronic Nephritis.—A case of chronic nephritis in a female child, four and a half years old, was reported by the President, Dr. Augustus Caillé. The urine contained renal elements, blood, casts, albumin and pus, was dark in color and scanty, fluid was present in the abdomen, and the eyes were puffy. She received hospital treatment consisting of diuretics and diaphoretics, with sweating and intestinal irrigation and was discharged much improved, but nine months later returned to the hospital, when the heart was found to be enlarged and general edema to be present. After a decapsulation of both kidneys had been done a typical chronic parenchymatous nephritis was found on both sides. Both kidneys were three times their normal size and over four inches in length. The patient made an uneventful recovery and there was no return of any of the previous difficulties. The author stated that in cases of this sort he would strongly advise inspection of the kidneys by lumbar incision, in the presence of a chronic nephritis which was not relieved within a reasonable time, that is, if no heart lesion was present. The hope of preventing an acute nephritis from becoming chronic would warrant splitting the capsule or decapsulating one or both kidneys, if they appear enlarged or swollen.

In reply to a question by Dr. Kerley, as to what effect such a procedure would have should these children contract scarlet fever or other infectious disease, the author said that as the procedure was a new one, little definite data had yet been gathered on these points. Many cases had been operated upon with marked benefit, as in the one reported, but the exact benefit conferred had yet to be determined, as to whether it was on account of increased blood supply or of the massage incident to the handling of the organ. But the results from the operations which he had seen were better than from those from medication.

Epidemic Vulvovaginitis in Infants and Children.—A paper on this subject was presented by Dr. A. C. Cotton, of Chicago. An epidemic of gonococcus infection occurred in a hospital from August 1902 to September, 1903, and during this time 319 children were admitted. A urethral discharge was first noted in a boy two years old, on August 8, 1902. Next a girl suffering from typhoid fever was found to have a vulvovaginal discharge containing gonococci. The epidemic would seem to have arisen from these two patients. It was the opinion of the author that every children's hospital should take special precautions against such infection, by maintaining detention wards where new patients may be isolated for at least two weeks to insure their freedom from infectious disease, and should symptoms of any such acute infection develop there should also be completely isolated wards where the patient could be immediately removed, and placed in charge of special attendants who should have no duties in the general wards. The same care should be used in the manipulation and treatment of a gonorrhea case that would be employed in regard to any other infection of an acute nature. Gonorrhea in a children's hospital was much to be dreaded, and female infants seemed to be exceptionally prone to contract it. Cases of a secondary involvement of the uterus or cervix, or a nephritis or pericarditis had been observed by Dr. Jacobi of New York, but in his opinion it was rather remarkable that undiapered children from two to four years of age did not more often carry infection to the eyelids.

In the Babies' Hospital, in New York, Dr. Kerley had seen some twenty cases of gonococcal arthritis in two years, and Dr. Jacobi had observed one case where a myositis was present.

Two cases of gonorrheal arthritis had been observed by Dr. L. E. LaFetra. In a baby three weeks old the source of infection appeared to be from the mother who had gonorrhea at the time of the child's birth. The second case was that of a child eight months old.

Dr. Caillé stated that at present every child admitted to the Post-Graduate Hospital in New York was thoroughly examined and a swab culture made, the child being refused if gonorrhea was found. This was done on account of the possible danger revealed by a suit brought against the hospital some years ago, when a child admitted in apparently good condition, ten days later developed a specific vulvovaginitis.

Acute Scarlatinal Nephritis Simulated by Carbolic Acid Poisoning.—The case of a child ten years old, who suffered from an attack of scarlet fever of moderate severity, was reported by Dr. S. S. Adams, of Washington. There were no alarming symptoms when he first saw the child on February 3, 1904. He instructed the mother to bathe her twice daily, using one teaspoonful of commercial carbolic acid to a quart of water, to allay the intense itching of which she complained. On visiting the patient ten days later very profuse desquamation had set in. the itching had been relieved by the carbolic acid baths, and there was apparently no tingling or irritation caused by them, so that the patient's condition was excellent. He received a report on February 22 that the child was in good condition, but had passed some dark urine, specimen of which he also received. This specimen contained granular casts, albumin, hyaline and red cells, and on visiting the patient her eyes were observed to be puffy. The baths being stopped the puffiness disappeared and the urine improved. It was Dr. Adams's conclusion that the patient had an idiosyncrasy against carbolic acid, as such a weak solution was employed, but he was satisfied from the urinalysis that the symptoms of nephritis were due to the carbolic and not to the toxic effects of the scarlatina, and the quick relief of the kidney irritation when the carbolic was stopped confirmed this.

Gastro-Intestinal Toxemia.—In the paper on this subject read by Dr. B. K. Rachford, of Cincinnati, the author drew a distinction between gastro-intestinal intoxication and auto-intoxication, inasmuch as the first was a systematic intoxication caused by poison formed and absorbed by the gastro-intestinal canal. The bacterial poisons produced in this canal way be caused by the components of dead bacteria, tuberculin for example, furnishing a certain amount of protein, by living bacteria excrating toxins or ferments, that can produce the most severe symptoms, or by substances produced by

the bacteria from the culture media. Ptomains are the most important of this latter class. The great irritability and the immaturity of the nervous system of the child or infant would probably account for the greater incidence of acute intestinal toxemia in patients of that age. A quantity of poison easily thrown off by an adult might produce high fever, convulsions and other symptoms of a pronounced nervous type in young children. The fact that the hydrochloric acid function of the stomach is less developed in the child than in the adult may also account for the greater frequency of severe albuminous fermentations, which are able to produce virulent toxins, as the stomach is on that account less able to control and prevent intestinal fermentation.

The author wished especially to direct the attention of his audience to chronic intestinal toxemia, as he considered this a most important etiological factor in the production of nervous symptoms and one to which proper attention is not often directed. Even when constipation exists this form may be associated with diarrhea. The food material should not be retarded, and the feces when ejected should have the moist form of a normal movement, as it is thus hyperfermentation and increased absorption of the poisons in the intestines may be prevented. The author regarded intestinal intoxication as so important a factor in the production of nervous symptoms in children, that he nearly always began his treatment of such affections by making a thorough examination into the condition of the intestinal canal. He mentioned hyperesthesia, psychoses, nervous anxiety, hysterical and neurasthenic symptoms, bradycardia, general nervous irritability, fever, malaise, heightened reflexes and anemia as symptoms which might be produced or increased by intestinal toxemia. The presence of indican and the ethereal salts in the urine offered valuable clinical confirmation of the diagnosis. Because of the general tendency to attach so great importance to vegetable organism in the production of intestinal toxemia the part played by animal parasites is often overlooked.

Dr. Jacobi mentioned the eating of raw vegetables, as in Germany and other European countries, as likely to produce such symptoms, and also spoke of the practice of the old text-books in ascribing them to "worms." He had also thought that a protracted anemia might cause disturbances of digestion by creating an insufficiency of gastric and pancreatic juices.

It was the opinion of Dr. Forchheimer, of Chicago, that the finding of indican in the urine was unimportant. He spoke of the retention of feces being followed by diarrhea in children, and he drew particular attention to a condition he had already described, occurring more often in adults then in children, a chronic ulcerative stomatitis, taking the form of Riggs' disease in adults. In Riggs' disease he had always found uric acid and thought it caused by some auto-intoxication.

Dr. Rachford thought that the presence of indican in the urine bore a relationship to that of indol in the intestine, indol being one of the results of putrefaction and formed in the intestinal canal by hypofermentation.

Fifty-One Cases of Acute Otitis in Children.—This series of cases was from the private practice of Dr. Charles G. Kerley, of New York, and was illustrated by several temperature charts.

SECOND DAY.—TUESDAY, MAY 31.

Nervous Exhaustion in Infants.—A paper was read by Dr. William P. Northrup, of New York, on several cases of nervous exhaustion in young infants which condition was the result of too great excitement from the attentions of admiring friends and relatives whose desire to "show off the baby" had often a most unfortunate effect upon the infant. He emphasized the necessity of quiet surroundings for young children, which are desirable particularly before and after the times of feeding, and called attention to the fact that injudicious attention on part of "grown-up people" is often responsible for nervous dyspepsia, sleeplessness and exhaustion in the overpetted baby.

Presidential Address.—Dr. Augustus Caillé chose for the subject of his presidential address the benefits conferred upon the children of America by the American Pediatric Society, and the objects toward which, in his opinion, the Society might well direct its future efforts. Among the points which he deemed especially worthy of the attention of pediatricians he mentioned the popular fear of "catching cold," which prevented many homes from receiving their proper share of fresh air. It is the duty of the physician to impress upon parents and those having children in their care the necessity of proper ventilation and temperature. The modern steam-heated dwelling was too often heated to a temperature far higher than it should be, and children living under such conditions are peculiarly liable to take cold. He recommended cold bathing and proper feeding with plenty of fresh air, as the surest method of combatting these tendencies. The duties of physicians in connection with disinfection after contagious diseases he regarded as most imperative, and often neglected or improperly performed. Infection is most easily conveyed among children, and such sources as the books of schools and libraries are all too often entirely neglected. Children recovering from such infections as diphtheria were compelled to stay indoors until all bacilli had disappeared from the throat, and they were thus deprived of the tonic effect of the fresh air which they greatly need. He regarded this practice as unreasonable and not founded on positive proof. He was also opposed to compelling the removal of children affected with the ordinary eruptive fevers to hospitals, as parents fearing this were in consequence impelled to conceal the existence of such diseases, and the danger of infection thereby greatly increased. He also made reference to the successful campaign which has been waged in favor of the medical inspection of public school children. The primary object of such inspection has been to detect the existence of contagious diseases, but its field of usefulness can still be vastly enlarged. It has already revealed many unsanitary conditions in all kinds of eduactional institutions, and has aided in the detection of skin lesions, parasites and so forth, but it should be extended to include a sort of hygienic guardianship of all school children. Children abnormal from any cause should be placed under the conditions demanded by their individual needs, and a great work lies before the physicians of America in aiding backward and neurotic children to advance under conditions suited to enable them to keep pace with normal children in perfect health. Such children should have separate class rooms and receive special care and instruction. The increased efficiency of the next generation would

more than repay the extra expense involved. In regard to children in good health it was the recommendation of the speaker that increased attention to be given to the subject of the bodily training of school pupils, and he regarded the playground as being of equal importance with the school room. Personal cleanliness should be one of the first principles inoculated, the foundation of the education of every child, and too much attention could not well be devoted to it. Regarding children's hospitals, it was his opinion that the physician's duty was not to encourage the crowding of cases of minor ailments or chronic affections into such institutions. Hospital life was highly detrimental to a child. In the New York Post-Graduate Hospital regulations had been drawn up for the prevention of house infection in the babies' ward. They are as follows: (1) Strict cleanliness of premises and inmates; (2) thorough ventilation; (3) plenty of air-space; (4) no overcrowding of the wards; (5) feeding of infants by a different hand than that attending to the toilet; (6) immediate removal and disinfection of soiled linen; (7) the toning up of feeble children by a change of air, or a sojourn in the roof-garden or sunbeam playroom.

The speaker than took up the consideration of the advances possible in the education of pediatricians. For undergraduate instruction he favored didactic lectures and bedside demonstration, and a strictly clinical basis for postgraduate work. The prominent features of a course in pediatrics should be dietotherapy and hydrotherapy, with physical diagnosis and laboratory work. His own plan of instruction for many years had been to devote two-thirds of the clinic hour to demonstration on a number of sick children so placed as to be readily accessible to the students, and the last part of the time to the discussion of important principles of treatment in the most common affections, or practical demonstration of such operations as tracheotomy, bowel irrigation, intubation or spinal puncture.

Summing up the suggestions made in the addresss Dr. Caillé offered the following set of headings, under which material might be gathered from year to year and presented in the transactions of the Society, thus making a running record of the world's progress in pediatrics. At each annual meeting the Council might appoint certain numbers who would be expected to furnish a critical review for the next meeting. The headings suggested were: (1) Home, school and hospital hygiene and prophylaxis. (2) Methods of teaching pediatrics. (3) Chemical, bacteriological and regional diagnosis. (4) General therapeutics, such as nutrition, diet, hydrotherapy, electrotherapy and phototherapy. (5) Surgical therapeutics, orthopedics and mechanotherapy.

(To be Continued.)

NORTH BRANCH PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, June 23, 1904.

The President, Samuel Wolfe, M.D., in the Chair.

Bone Passed per Rectum.—Dr. Anna M. Reynolds exhibited a specimen of bone passed per rectum by a woman who six years before had fallen downstairs and struck her left side, it being six months thereafter before she felt all right; on physical examination, the lower rib on that side cannot be found and the specimen looks very much like a rib.

Case of Displaced Heart.—Dr. Harry Löwenburg exhibited a case of displaced heart, following pneumonia, occurring in a child whose father died of tuberculosis. The child has been somewhat weak since the age of nine years, when he had pneumonia, having also been treated for fracture of the scapula. The apex beat is located on the right side, in the position it should have occupied in the left. The skiagraph of the case was exhibited by Dr. Geo. E. Pfahler.

Syphilis Insontium.—Dr. Harry Löwenburg also exhibited a case of syphilis insontium occurring in a girl nine years of age, who, when first seen, had a pimple on the right thigh which proved to be an initial sore. General glandular enlargement followed, accompanied by primary eruption and other evidences of syphilis.

Dr. Alfred Hand, Jr., reported a case of tuberculosis of the right lung occurring in a little girl in which the heart has assumed the dextra position.

Dr. S. Leon Gans felt that it would be interesting to know whether the sore in Dr. Löwenburg's case was originally a chancre, or whether it was an abrasion of the skin which had been infected with syphilis.

This was followed by a

SYMPOSIUM ON SUMMER DIARRHŒA OF CHILDREN.

The Etiology of Summer Diarrhea of Children.—Dr. Alfred Hand, Jr., read this paper. He stated that the disease was undoubtedly of infectious origin and that of the causative factors three stood out with striking weight: (1) summer-time, (2) infancy, and (3) bottle-feeding; the first being mainly dependent upon the delicate anatomic structure and immature physiologic functions. He stated that out of 636 cases of diarrhea in children from 1896 to 1902, in his dispensary service at the Children's Hospital, 12 per cent. occurred in May; 36 per cent. in June and 52 per cent. in July. The heat exerts its influence by lowering the resisting power of the individual and favoring the multiplication of bacteria in milk and water, which is particularly emphasized in large cities, due to the heat, stale atmosphere filled with dust and germs, and the age of the milk supply. He laid especially emphasis on the importance of cleanliness in the production and handling of the milk. He referred to the work of Shiga and Duval with the dysentery bacillus, the latter having demonstrated that out of 42 cases of summer diarrhea in infants, every one gave positive results as to the dysentery bacillus; and out of 20 cases in his wards at the Children's Hospital last summer, 12 gave positive results. He remarked that the bacillus had been isolated from water, and referred to the views of Knox and Newsholme as to the relationship between the drainage of the community and the number of cases of summer diarrhea.

Prevention of Summer Diarrheas.—This paper was read by Dr. Samuel McHamill, in which he considered as factors entering into the production of these conditions: (1) The atmospheric conditions—excessive heat, humidity and sudden fall in temperature, which act in two ways, first by increasing the bacterial contents of the milk, and second, by reducing the resisting power of the individual, the latter of which should be protected as much as possible by regulation of the clothing of the child, taking it to the country or keeping in shade, etc. (2) Defective conditions of hygiene rendering the food

liable to contamination and causing the child to suffer from lack of sufficient light and air, which should be remedied by keeping the child in the street or park, etc., as much as possible. (3) Defective conditions of the soil, resulting from dusty and torn up streets. (4) Lowered resistance from infections or nutritional disturbances, which should be guarded against by careful regulation of the diet, particularly as to digestibility, cleanliness and regular adminstration. He stated that mother's milk was the best food for the infant, and when cow's milk must be substituted, recommended that careful attention be paid to the sanitary and hygienic production thereof, as the toxic products in unclean milk can only be destroyed by a degree of heat which renders its nutritional value less. He also recommended careful attention to the nursing bottle which should be thoroughly cleansed after each nursing. Proper bathing should also be given careful attention, and water, always boiled, should be allowed freely but not within one and one-half hours from the preceding meal.

The Treatment of the Summer Diarrheas of Children.—Dr. H. Löwenburg read this paper. He considered under the following heads: (1) Prophylaxis, (2) Dietetic treatment, (3) mechanical treatment, (4) Medicinal treatment, (5) Serum treatment. Under the head of prophylaxis he regarded as the most important factors, summer heat and improper feeding. The sleeping apartments should be cool and well ventilated, and the bed covered with mosquito netting in order to prevent the contact of flies and influence of drafts. Cool bathing is also of value. The feeding of the infant should be at regular intervals, and, if possible, breast-fed; if not, pasteurized milk, if obtainable, or in the event this cannot be secured, the milk, as well as all water entering into its composition, should be boiled, the exact composition of the food to be governed by the particular case. Careful attention should also be given to the cleansing of the nipple and nursing bottle. As to the dietetic treatment, all milk should be discontinued, upon the beginning of an attack, for twenty-four to forty-eight hours, sterile water being administered at short fixed periods, preferably, if tolerated, albumin water, to which may be added expressed beef juice or brandy, and in severe cases the child must be maintained on nutrient enemata for twenty-four to forty-eight hours. The use of milk, preferably peptonized of slight strength should be gradually resumed and the strength increased. The mechanical treatment consists of lavage in cases of uncontrollable vomiting; colonic irrigation when incomplete emptying of, or combined with silver nitrate solution 1:1,000 when there is ulceration of the bowel; and hypodermoclysis in cases of cholera infantum during the stage of collapse following excessive purgation. The medical treatment consists of purgatives, such as castor oil and calomel, combined with intestinal irrigation in the fermental type of diarrhea; following this are administered the intestinal antiseptics consisting of salol, zinc sulphocarbolate and copper arsenic, which, however, have not been attended with success on account of the inability to administer them in large doses; and the intestinal astringents and sedatives such as morphia, bismuth and atropia. The serum treatment he stated was still in its experimental stage and referred to the paper read by Holt at the recent meeting of the American Medical Association.

Dr. James H. McKee, in the discussion, stated that there were a number of instances in which the streptococci had been found in milk, and referred to the work of Eskridge, Vaughan, Baginsky, Holt and Parke in this direction. As to the finding of the dysentery bacillus, he believed that there was no doubt of its presence in these cases, but the frequency varied considerably according to different observers. He stated that while he did not believe pasteurization or sterilization could replace a pure milk, these measures were of immense value, and also remarked that he had seen a number of cases of milk infection produced by pure milk. In the treatment of the cases, he recommended the withdrawal of all food and the administration of barley water for forty-eight hours, after which the resumption of milk should be gradual. In cases of fermentative diarrhea, he recommended the administration of calomel at first with castor oil later on, and the witholding of milk; in severe cases enteroclysis of normal salt solution were recommended. In these cases milk should not be resumed within forty-eight hours, but barley jelly may be administered on the third day, followed by animal broths.

Dr. Theodore LeBoutillier referred to the large amount of bacteria in the ordinary milk supply, and referred to the case of a patient who was taken with a slight attack of diarrhea which he attributed to the milk, which upon examination was shown to contain streptococci. In regard to pasteurization, he believed the home modification, if possible, to be carried out was better than the laboratory method.

Dr. W. H. Ruoff referred to the danger of producing diarrhea from bichloride of mercury formed by the giving of calomel followed by enemata of normal salt solution, and believed codeine to be preferable to morphine for a soothing effect.

Dr. William H. Good did not feel that if the calomel had not changed when passing through the gastric contents it would do so when it reached the sodium chloride as outlined by the last speaker.

Dr. H. Brooker Mills referred to the fact that he had observed the almost universal use abroad of a bottle with a long rubber tube, and that there was no more trouble there than in this country where we do away with the attachments.

Dr. McHamill, in closing, stated that sterilization should be used only as a temporary procedure, and that at the present time all ordinary milks were of such a character as to require pasteurization. He believed that if certified milk was used in winter we should be able to use it in summer without pasteurization. He remarked that the certified milk seemed to suffer more in March than any other month, which he attributed to the fact of the sudden changes of weather and insufficient icing to stand the same.

Dr. H. Löwenburg, in closing, stated that, while possibly pasteurization and sterilization might not be the best methods of destroying the organisms and modifying the toxins he felt they were the best available for the poorer classes. At the same time while it is recognized that both pasteurization and sterilization made some changes in the chemical character of the milk, rendering its digestion more difficult, it was highly probable that the bacterial disinfection was more helpful than the digestion modification was deleterious, and therefore these procedures represented minor ills. He did not believe there was any danger as suggested in the administration of calomel followed by saline enemata.

BOOK REVIEWS.

A System of Practical Surgery. By Prof. E. von Bergmann, M.D., Prof. P. von Bruns, M.D. and Prof. J. von Mikulicz, M.D. Volume IV. Translated and edited by William T. Bull, M.D., Professor of Surgery, College of Physicians and Surgeons, Columbia University, New York; Edward Milton Foote, M.D., Instructor in Surgery, College of Physicians and Surgeons, Columbia University, New York; Carleton P. Flint, M.D., Instructor in Minor Surgery, College of Physicians and Surgeons, Columbia University, New York, and Walter Martin, M.D., Instructor in Surgery, College of Physicians and Surgeons, Columbia University, New York. Surgery of the Alimentary Tract. Lea Brothers & Company, New York and Philadelphia.

The list of contributors to this, the fourth, and in some respects the most important volume of von Bergmann's great system, comprises many illustrious names. Graser, v. Hacker, Kausch, Kehr, Körte, Lotheissen, v. Mikulicz, Schlange and Steinthal, are responsible for the original text which has been most ably translated and adopted for use in this country by the American editors. The latter have also expended much effort in enriching the already admirable collection of engravings and colored plates, so that in its present form the volume is undoubtedly one of the most beautifully and usefully illustrated books on surgery in existence.

The first section, by v. Hacker and Lotheissen, deals with the surgery of the esophagus and includes full information in a branch as yet but little developed in this country, viz., esophagoscopy. The technic of the procedure, together with the deductions to be made from its employment, are described at length and elucidated by a colored plate reproducing the pictures seen in the esophagoscope in various diseased conditions. The important subject of stricture in this region is also discussed at unusual length and the many methods of treatment devised by the ingenuity of different surgeons are well depicted and described. Steinthal contributes the section on the injuries and diseases of the abdominal wall, which is followed by a consideration of similar conditions in the peritoneum by Körte and a most suggestive section on laparoptomy by v. Mikulicz and Kausch. It is interesting to note that ether is recommended as the anesthetic of choice, an indication of the changed point of view in regard to chloroform beginning to prevail abroad. Special anesthesia is relegated to exceptional cases. The same authors have written the chapters relating to the stomach and intestines which include some of Prof. Huntington's valuable plates on the development of the appendix. The section on hernia, by Graser, has also been much improved by the addition of new illustrations. The important subject of the liver and biliary passages has been allotted to Kehr, who has produced a most satisfactory abstract of the results of his wide experience. The detailed diagnostic table for the differentiation of lesions of this region should prove very helpful in practice. The authority of the succeeding section in the spleen is not stated and the volume closes with Körte's valuable chapters on the pancreas.

The surprisingly rapid appearance of the different volumes of this magnificent work indicates unusual energy on the part of all those concerned in its production and we congratulate them on the brilliancy of their performance.

The Doctor's Leisure Hour. By Charles Wells Moulton, General Editor. Arranged by Porter Davis, M.D. Saalfield Publishing Company, Akron, Ohio.

A well-bound, broad-margined book, inviting to the laity as well as to the profession, this first volume of "The Doctor's Recreation Series" comes to stimulate the risibilities and to rouse anticipation of the remainder of the series.

The book is divided into some thirty odd chapters with headings such as "The Patient," "The Doctor's Horse," etc., and grouped with admirable selection under each are humorous poems, anecdotes, and the innumerable and venerable jokes upon doctors, students, and weary patients; interspersed from time to time are appropriate chapters from well-known books such as MacLaren's "Doctor of the Old School."

As the preface states, the articles "are not confined to the funny side of physic but include many pages of weighty and instructive matter." This, however, being not more ponderous than selections from the reminiscences of Oliver Wendell Holmes, descriptions of medical life in the past, and some short essays, holds the attention even more satisfactorily than the poems and anecdotes, many of which having served long and faithfully in the cause, though dear to the heart and venerated for their hoary age, are nevertheless beyond the power of even the Fountain of Youth to rejuvenate.

Most of the matter is very entertaining, and all of it, both the new and the old, has point. It is delightful for a half hour after dinner and makes an able assistant in the waiting room. Principally it is unlike most collections of medical witticism in that it may safely be left on the office table within reach of "the Young Person." The one regrettable thing is the pictures, of which there are fortunately few, and it is to be hoped that in the succeeding volumes for recreation they will be omitted unless they pertain more strictly to the subject-matter.

BOOKS RECEIVED.

THE TREATMENT OF SCARLET FEVER WITH THE MOSER ANTISTREPTOCOCCUS SERUM.

BY HENRY L. K. SHAW, M.D.,

OF ALBANY, N. Y.;

LECTURER IN PEDIATRICS, ALBANY MEDICAL COLLEGE.

FOR the last four years all the severe cases of scarlet fever admitted to the Annakinderspital in Vienna have received the Moser serum with results not less remarkable than those seen after the use of diphtheria antitoxin. As this method of treatment is little known in America, an account of the preparation of the serum, the mode of employment and the results following its use may be of more than passing interest.

While the definite cause of scarlet fever has not yet been discovered with absolute certainty, for more than twenty years the claim has been made that it was due to a streptococcus. The literature on this point is now quite voluminous, and two general views are taken. Baginsky, D'Espine, and Moser believe that scarlet fever is primarily due to a streptococcus, while Heubner, Marmorek, Slawyk, Pearce, and others claim it is produced by an agent as yet unknown. The supporters of this latter view admit that the streptococcus is the most constant micro-organism found, but they explain its presence as the result of some secondary infection. A theory has recently been advanced that scarlet fever is produced by a symbiosis of the streptococcus and the unknown virus.

Courtois found streptococci in the urine of 91 per cent. of scarlet fever cases with aluminuria, and in 27 per cent. of cases without albuminuria. Charlton[1] detected streptococci in the tonsils and pharynx in 55 per cent. of his cases, and invariably in the blood of the most severe cases during the first five days of the disease. Baginsky[2] cultivated streptococci either alone or associated with other bacteria in 411 out of 696 cases, and in 82 fatal cases streptococci were found in all the organs in every instance. Hektoen,[3] who is doing some valuable work along this line in America, was only able to demonstrate streptococci in the blood of living scarlet fever patients in twelve per cent. of his cases.

Moser,[4] working in the Annakinderspital in Vienna from 1897 to 1902, was able to obtain pure cultures of streptococci in the heart blood of 63 out of 99 fatal cases, and twice in the cerebrospinal fluid of living children. From his investigations he believes that some direct relationship exists between these streptococci and the etiology of scarlet fever. In support of this view he has recently shown[5] that streptococci from scarlet fever patients agglutinate in a positive specific manner with the immune serum, and Schick also found that streptococci from the throats of uncomplicated cases agglutinate positively with the Moser serum. Weaver,[6] on the other hand, claims this agglutination is in no way specific, and is of no value as a means of diagnosis.

Behring and Marmorek both demonstrated that specific immune bodies appeared in the blood of animals inoculated with streptococci. Marmorek, believing that the streptococci were the result of a secondary infection, was the first to attempt to treat scarlet fever by injecting antistreptococcus serum. He obtained the streptococci from other sources than scarlet fever cases, and first cultivated them through animals before he inoculated horses. The use of this serum did not produce the anticipated favorable effect on the course of the disease. Aronson, in Berlin, obtained a serum from streptococci from the throats of scarlet fever patients, which were passed through animals until they had reached a high virulence similar to the method employed by Marmorek. Baginsky gave this serum a thorough trial without satisfactory results.

Meyer was the first to show that streptococci passed through animals lose their earlier agglutination power with a certain serum, and Petrusky and Koch recently pointed out the fact that in the passage through rabbits the virulence of Marmorek's streptococci was increased toward rabbits, but decreased toward man.

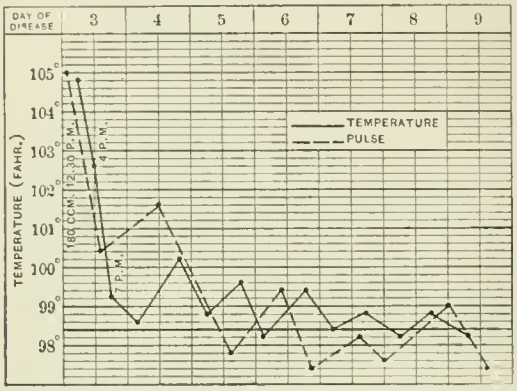
Moser employs a different method in order to prevent any biological changes in the streptococci. The horses receive injections of bouillon culture of streptococci direct from the child. Up to the present time he has isolated nearly 30 different types of streptococci, and as he injects them all his serum is a true polyvalent one. He has also shown that these streptococci differ from those found in the other streptococcic diseases of man, such as erysipelas, etc.

The steps in the production of this serum, briefly, are as follows: An ordinary bouillon culture is made from the heart blood of a fatal case of scarlet fever, and grown for three to six days. It is then injected subcutaneously into the horse. This produces a slight reaction with fever, etc. These injections of cultures from different cases are given over a week in gradually increasing doses. It takes seven to nine months to produce a suitable serum, and some horses are never able to produce a satisfactory serum. No carbolic acid is used to preserve this serum. When sufficiently potent, the serum, in a dilution of 1 to 250,000, should agglutinate the streptococci.

Freund,[7] chief of the chemical laboratory of the Wiener Rudolfs-Stiftung, isolated a poison in the stools of scarlet fever patients, which was toxic to mice. Several doses of this toxin were injected in mice with one cubic centimeter of the Moser serum. The serum protected these mice while the control mice all died.

All scarlet fever patients received at the Annakinderspital are classified on admission accord-

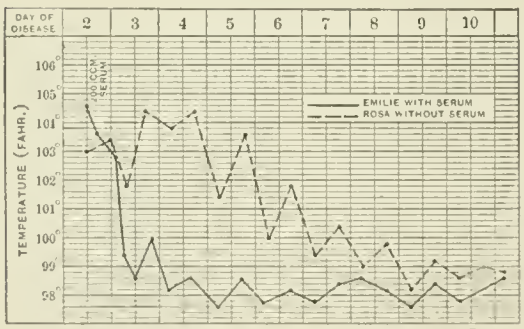
CHART 1.



John Lachner, aged two years. Group III type.

ing to the severity of the case. Group I includes the mild cases, Group II more severe cases, with high fever; Group III, very severe cases, with symptoms of general intoxication, and Group IV, the lethal cases, in which there is apparently no chance of recovery. The serum is generally employed in cases classified under the last two groups. The serum is injected subcutaneously in the abdomen. At first 30 c.c. were given, but

CHART 2.



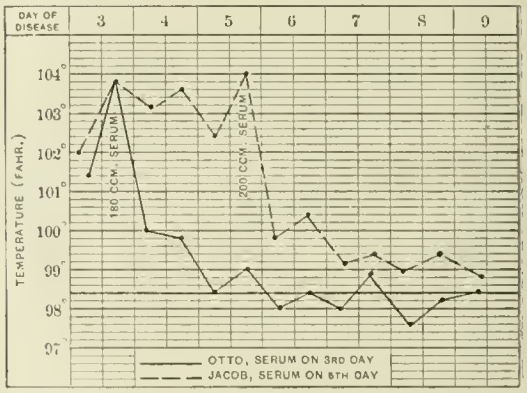
Rosa S., aged eight years, and Emilia S., aged six years. Group II type.

it was later found that larger doses were necessary, and now 200 c.c. are given as a dose. This is a much larger amount than is employed by Marmorek or Aronson, but no bad results save the serum exanthem has been observed. A second injection is very rarely necessary.

The results from the serum are noticed within a few hours. The fever falls to normal without any signs of collapse or sweating, the pulse rate diminishes, and its quality is improved, the symptoms on the part of the central nervous system rapidly subside, and there is a marked and perceptible improvement in the general condition of the child. In short, all the symptoms of a general toxemia rapidly disappear. The effect on the temperature and pulse can be seen in the accompanying chart. Chart 1 is from a child two years old, who was admitted on the third day of the disease with a severe Group III type. The temperature was 104.8° F., and the pulse 160 before the injection of 180 c.c. of the Moser serum.

The rapid fall in the temperature and pulse rate is very marked. This chart can be said to be typical of the effect of the serum on severe cases of scarlet fever. It does not demonstrate, however, the great improvement in the mental and physical condition which is so convincing to those who are able to follow the course of the disease. For the purpose of comparison, ejections of 200 c.c. of normal horse serum have been given sev-

CHART 3.



Otto W., aged eleven years. Group III type. Jacob W., aged thirteen years. Group II type.

eral times without producing any effect on the temperature or course of the disease. Marmorek's serum has also been employed without any noticeable effect.

A more striking demonstration of the effect of this serum is seen in Charts 2 and 3. Chart 2 shows the temperature curves of two sisters, aged six and eight years, who were brought to the hospital on the same day with a Group II type of scarlet fever. The child with the highest temperature, 104.6° F., was given 200 c.c. of the serum, and the temperature fell rapidly. The disease ran an ordinary course in the sister, who did not receive the serum.

Chart 3 shows the curves in two brothers, one of whom, on admission, had more severe symptoms than the other. He received 180 c.c. of serum, and made a rapid recovery. The uninjected brother, however, grew worse, and it was necessary to give him serum on the fourth

day. Charts like these could be greatly extended, but enough are shown to illustrate the striking effect of the Moser serum on the course of scarlet fever.

Sequelæ and complications have been less frequent since the use of the serum, and when they do occur they are less severe. No fatal case of nephritis has occurred in any of the injected cases.

From November, 1900, to July, 1904, 1,069 cases of scarlet fever have been admitted, and of these 228 received the serum. The severe and lethal cases are invariably injected. The mortality for four years before the serum treatment averaged 14.5 per cent. and for the four years since its employment the mortality averaged 8 per cent., whereas for the same period in the other scarlet fever hospitals in Vienna the mortality where the serum was not used averaged 13.1 per cent.

The only unpleasant result following the use of this serum is the serum exanthem. This is often accompanied with fever, and while it is not at all dangerous, it makes the children very uncomfortable. Little is known as to the cause of this serum sickness. The younger the child the more pronounced are the symptoms, and the smaller the quantity of serum injected the less apt is the exanthem to follow. Serum sickness followed the injection in 73 per cent. of the cases.

Moser injected 10 c.c. of the serum as a prophylactic measure in fourteen children in private families, who had been exposed to scarlet fever, and of these four came down with the disease. The attacks in all these cases were lighter than the ones to which they were exposed. A more instructive example was afforded in one of the hospital wards where twenty-five children were exposed. They all received a prophylactic dose and not one contracted scarlet fever. While the number of cases in which a prophylactic dose has been given are too few to give conclusive proof of its value, yet the results so far accomplished are most encouraging.

A comparison of the mortality rate from diphtheria and scarlet fever for the past ten years in the Annakinderspital illustrate the beneficent effect of serum therapy in both diseases.

Year.	Diphtheria. Per cent.	Scarlet Fever. Per cent.
1893	44.4	25.2
1894	43.	21.
1895	18.4 *Serum*	20.
1896	17.4	17.6
1897	13.6	11.1
1898	11.3	12.3

1902	8.1	6.7
1903	6.5	8.5
	January 1 to July 1, 1904.	7.6

At the present time this serum is prepared only at the Vienna Serum Institute, and is not on the market. For this reason its use has been necessarily limited, and only a few clinical tests have been made outside of the Annakinderspital. Pospischill,[8] of the Wilhemina Hospital, received a supply of the serum and reported on twenty-six cases of scarlet fever thus treated. They were all of the most severe type, and eleven terminated fatally. Several apparently hopeless cases recovered, and in the conclusion of his article Pospischill testifies to the value of the serum treatment, and says that "fall in the temperature, pulse rate and respiration, increased volume and tension of the pulse, brightening of the intelligence, peaceful sleep, return of warmth of the extremities with disappearance of cyanosis, and an improvement in the appetite, are the most marked and constant results of the injection."

Bokay,[9] of Budapest, was provided with some serum, and employed it in twelve of his most severe cases. Two of these died. He observed the same effect on the temperature, pulse and nervous system, and said that, while he could not give a final judgment from so few cases, yet his impressions were most favorable, and he was convinced that the Moser antistreptococcus serum had a real antitoxic action on the course of scarlet fever. Knöpflelmacher has also used this serum with most satisfactory results in the Carolinakinderspital in Vienna, but has not yet published his experience.

Professor Escherich took charge of the Annakinderspital in 1902, and was rather sceptical about the efficacy of the serum treatment, but he later became thoroughly convinced as to its value, and is now an ardent advocate of the treatment. His paper[10] before the International Medical Congress at Madrid is a fair and convincing argument in support of the Moser serum.

I wish to express my gratitude to Professor Escherich and to Dr. Moser for their kindness in affording me an opportunity to watch the effect of the serum treatment in the scarlet fever wards.

A CASE OF TYPHOID FEVER WITH REPEATED CHILLS.[1]

BY JOHN HOWLAND, M.D.,

OF NEW YORK;

ASSISTANT PHYSICIAN, ST. VINCENT'S HOSPITAL; ATTENDING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS; PATHOLOGIST TO THE NEW YORK FOUNDLING HOSPITAL.

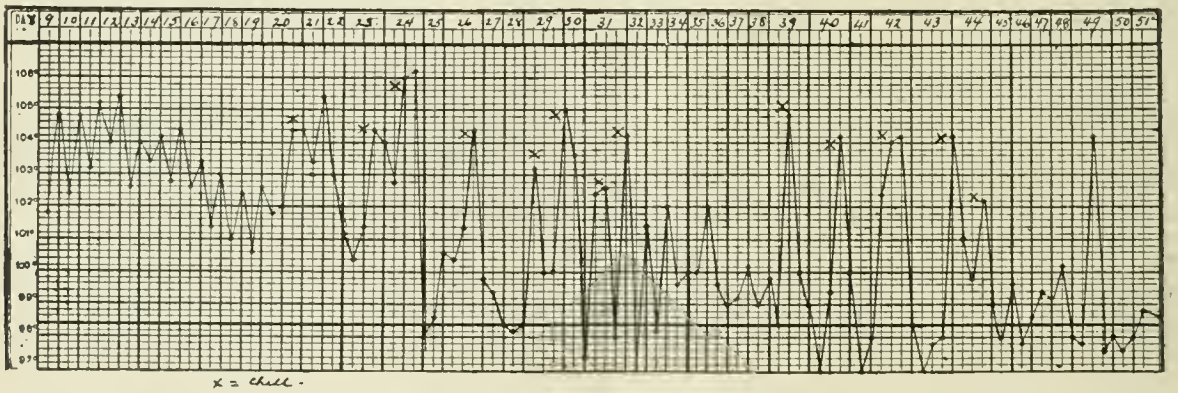
CHILLS in typhoid fever, while not uncommon, are rarely repeated or of great severity. A chilly sensation, sometimes a distinct chill, may usher in an attack, and at any time during the course of the disease the onset of a complication, especially one associated with the formation of pus, may be heralded by a distinct chill. Coincident malaria, especially toward the end of an attack, may produce its characteristic chills, and finally, chills may come in the course of the disease and even in convalescence, nothing being found to explain their occurrence. To this last class the case that I report evidently belongs.

The patient, a male thirty years old, was admitted to St. Vincent's Hospital on July 16, 1903. His family history was good. He was a moderate user of beer, whisky and tobacco. He denied any venereal disease. He had never been seriously ill before, and had suffered from nothing but the usual diseases of childhood. His present illness began about one week before his admission, with weakness, loss of appetite, and vertigo. He had headache, but no nose-bleed or vomiting, his bowels were regular and his stools apparently normal. For three days he had been sick enough to be in bed and have a physician, and at the end of that time, not seeing any improvement he came to the hospital. On admission his temperature was 103.8° F., his pulse 100, and his respirations 30.

Physical examination showed the patient of moderate size, fairly nourished and not anemic. His tongue was moist and coated. The heart was normal and also the lungs. The pulse was regular and of good quality, without arterial thickening. The liver percussed from the fifth space to the free margin. The edge was not felt. The spleen was readily palpable one inch below the free margin of the ribs and was slightly tender. His abdomen was not distended, but was sparsely covered with typical rose spots. His urine gave a marked reaction for indican and his blood a strong Widal reaction in a dilution of 1 to 50. He was put on the usual typhoid treatment and was given sponge baths for a temperature of 102.5° or over.

For the first week there was nothing of note, his condition remained good, his temperature varied between 102.5° and 104.6° F., being fairly controlled by sponging. His pulse remained about 100 and of good quality, and he received only one-half ounce of whisky every four hours.

On the tenth day after his admission, approximately the seventeenth of his disease, his temperature dropped to 101° F. and remained low for three days and everything seemed favorable. Then on the twentieth day of his illness he had a severe shaking chill, lasting one-half hour, followed by a rise of temperature to 104.2° F. Nothing abnormal could be discovered, especially were the lungs clear. At this time the urine contained a trace of albumin with a few granular casts. No malarial organisms could be found in the blood after repeated search and his leucocytes were 7,600. The following day, the twenty-first, he had no chill, but his temperature rose to 105.4° F.



On the twenty-third day he had another chill, and on the twenty-fourth still another, followed by a temperature of 106.2° F. With this last chill he became much cyanosed and did not react well, so that for the succeeding temperature no bath could be given, and it was necessary to put him in a hot pack. Careful examination twice a day failed to reveal any cause for the chills. These were repeated on the twenty-sixth and twenty-ninth days, on which latter day he had two. On the two days between the temperature was nearly normal, and between the chills his general condition was fair, but during and after the chills he seemed almost *in extremis*. On the thirty-first day there were two more chills, but from then on for eight days, only a slight irregular temperature, usually under 100° F. The chills were repeated on the thirty-ninth, fortieth, forty-second, forty-third and forty-fourth days, followed each time by a temperature of 104° F. or over, and once a drop to 96° F. in four hours.

On the forty-first day he developed a femoral thrombosis of the right leg, which was tender and caused some edema, but did not otherwise compli-

cate matters. Frequent examination of the blood failed to show a leucocytosis, a blood culture was negative, and nothing additional could be detected. The patient became very much emaciated and so, irrespective of the chills, was fed on eggs and junket, with toast and scraped beef, in addition to the milk.

There was a cessation of the chills from the forty-fourth to the forty-ninth day, when the last one took place, being apparently as severe as any of the others, and followed by a temperature of 104.2° F. After this there were no more chills, but occasional elevations in temperature.

It will thus be seen that there were 14 distinct chills, all followed by a marked rise of temperature. In endeavoring to account for them we may, I think, disregard malaria. Repeated examinations of the blood failed to show organisms, there was no periodicity about the attacks and the exhibition of quinine, ten grains three times a day, had no effect upon them.

The signs of complications were looked for in vain, the lungs were always clear, the bones, the gall-bladder and kidneys never gave any signs of involvement and there was never any leucocytosis. The one abnormality recognized was the femoral thrombosis, but it would be difficult to hold this responsible for all the trouble, as the chills began twenty-two days before its appearpearance and there was none on the day that it was first seen.

We can then do no more than say that this was a case of typhoid fever with repeated chills of unknown origin.

OSTEOPLASTIC GASTROTOMY FOR IMPERMEABLE CICATRICAL STRICTURE OF THE ESOPHAGUS.

BY WILLY MEYER, M.D.,

OF NEW YORK;

ATTENDING SURGEON TO THE GERMAN HOSPITAL; CONSULTING SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL AND TO THE NEW YORK INFIRMARY FOR WOMEN AND CHILDREN.

In view of the very recent introduction of osteoplastic operations as a means of reaching hitherto inaccessible parts of the organs situated within the cavity of the diaphragm, the following case may be of interest:

S. F., male, fourteen years of age, swallowed a large quantity of caustic lye, by mistake, in February, 1896. He was immediately taken to a neighboring hospital, where the stomach was washed out. It was necessary to resort to rectal feeding. Ten days later he was admitted to one of the city hospitals, where gastrotomy and division of the stricture by Abbe's string method, at the same sitting, were done one month later. Under suitable after-treatment the boy was soon able to take food again by way of the mouth. He remained at the hospital about a year, a bougie being introduced every few days and left in the esophagus for twenty-four to forty-eight hours, while the patient swallowed his food alongside the instrument. But in spite of all that was done, the esophagus showed great tendency to recontraction. By the end of the year the stricture had reformed, and a gastric fistula, according to Witzel's method, had to be established. All attempts at passing the esophagus from above or below were unsuccessful and the boy had to be fed entirely through the gastric fistula. This was kept up for seven years, when the mother, anxious that something should be done for the relief of the boy's condition, brought him to the German Hospital in September, 1903. On examination it was found that the stricture in the esophagus was absolutely impermeable. Then, with the view of perhaps facilitating the finding of an entrance from above, Dr. Torek (at that time in charge of my service) established an esophageal lip-fistula; but this, too, proved of no avail.

When I first saw the patient, September 21, 1903, the entrance into the stricture was so tight that it was impossible to pass even a filiform bougie into the stomach by way of the esophageal fistula. The instruments could be pushed forward for about two inches and then became bent. The retrograde passage was, therefore, tried. After thorough irrigation of the stomach, and filling the latter with water, the electric cystoscope was introduced through the gastric fistula and attempts made to locate the cardia, but without success. At the site of the cardia was an irregular scar, surrounded by a zigzag line, but no lumen could be detected anywhere. The same negative result was met at repeated subsequent sittings. Thereupon the direct view with the help of the Rochester cystoscope—the stomach being filled with air—was tried, but also in vain. Our endeavor to find and enter the cardia with a long urethro-endoscope, likewise, failed. The idea of gaining entrance to the esophagus from the stomach, therefore, had to be given up.

Hence, the route through the esophageal fistula again was tried. Kelly's cystoscopic tube (No. 10), with the boy's head in a hanging posture and turned to the right, was pushed forward until resistance was met with. A small electric lamp, on a curved handle, was then introduced into the tube, down to its distal end and thus the upper entrance into the stricture could be clearly seen. The picture presented the exact appearance of a cervix uteri, that is to say, there was a mass, evidently made up of scar tissue, projecting upward into the lumen of the esophagus, showing in its middle a minute hole, from which bubbles of air were pressed out in coalition with respiration. This spot was probably about one inch above the bifurcation of the trachea. A fine probe passed for a distance of about one half inch. Efforts to distend the canal with fine laminaria tents and to push down (of course, with moderate force) a straight metal probe, as the passage of flexible bougies was always quickly arrested, were continued for the following eight to ten weeks.

As the procedure, however, became too painful and general anesthesia was required for each sounding, it was thought best to have but one sit-

ting a week, so as not to overtax the already greatly reduced strength of the patient. It was found during these maneuvers, that the lumen of the esophagus was curved at various places. Generally, on deep inspiration only, the instrument slipped down further and further. By the beginning of December the probe passed down the esophagus to such length that it should have entered the stomach, according to measurement made, after withdrawal, on the outside of the chest. It was therefore inserted again and the cystoscope introduced through the gastric fistula. But the tip of the probe could not be detected in the stomach, nor could it be reached by means of curved metal probes passed in the same

Sidney F.—Osteoplastic gastrotomy. Curved scar shows line of incision. Below the same scar resulting from former gastrotomy and gastrostomy; exit of tube at inner angle. On the neck esophageal lip-fistula.

way. It was therefore concluded that the probe must have entered a false passage and have been arrested above the diaphragm.

In this emergency I resolved to raise the left border of the ribs by means of an osteoplastic operation, as recently described by Marwedel.[1] Of course, the task here was somewhat different from that in the operations mentioned by Marwedel and Asthoewer, who had done two somewhat similar operations several years previous.[2] In my case it was necessary to avoid interfering with the gastric fistula, if possible, and keep the stomach firmly attached to the abdominal wall. The incision parallel with the border of the ribs up to the ensiform process could not be carried out.

The operation was done on December 21. As the accompanying illustration will show, a U-shaped incision was made, the tip of the anterior leg corresponding to about the middle of the cartilage of the seventh rib, the convexity dividing the skin just below the border of the ribs. After the skin covering the region of the gastric fistula had been well pulled down in order to reach tissue that had not yet become interwoven with the scar, the tip of the posterior leg of the U crossing the outer end of the cartilages of the tenth, ninth, eighth and seventh ribs, it was possible to enter the abdominal cavity about one-half inch above the gastric fistula. The seventh cartilage having been divided with a knife near the sternum and those of the other ribs on the outer side, likewise, it was possible, by means of sharp retractors, to raise the flap sufficiently to allow a good view of the wall of the contracted stomach about 1½ inch above the region of the gastric fistula.

For reasons not apparent at that time, the flap did not yield sufficiently to permit of proper access to the cardia. As it was absolutely necessary to keep the gastric fistula intact, this point was not pressed. According to the plan of operation previously arranged, the patient was now placed in a pronounced Trendelenburg posture and the entire subdiaphragmatic space on either side of the stomach well packed with loose aseptic gauze in order to avoid soiling the peritoneal cavity. Two silk threads were now passed through the gastric wall, serving as retention slings, and the stomach was pulled into the wound on the outer side of the gastric fistula, the position of the patient remaining undisturbed. A horizontal incision about two inches in length was then made into the stomach. The further procedure resembled prolonged intravesical work after suprapubic cystotomy. Large blunt retractors were introduced into the stomach and the depth of the organ was unfolded by means of sponges on a handle.

With the small electric light the region of the cardia could be very closely inspected, but the cardia could not be seen. There appeared in the upper part of the fundus, about one inch to the left of the spot where the cardia ought to be, a minute hole, from which, at times, a few bubbles of air were seen to emanate, just as we had perceived them at the upper entrance in the esophagus. Perhaps this small hole was the cardia, drawn aside by cicatricial contraction or it had to be looked upon as the lower end of a false passage made with the metal probes so frequently passed. Various kinds of instruments introduced into the same met with an insuperable resistance. There, furthermore, was to be seen at the normal site of the cardia that stellated scar, observed before with the electric cystoscope. After this vain search for the cardia the stomach was temporarily

1 Centr. f. Chirurgie, 1903, No. 35, p. 938.
2 Ibid, p. 125.

packed with gauze, the table lowered and a metal probe, introduced from above by means of the Kelly cystoscope, gently pushed down as far as we had succeeded in gaining a passage for it on former occasions. This was firmly held in place by an assistant, the patient's pelvis again raised and, with a finger in the stomach, the lower end of the probe was searched for, but could not be felt. Evidently its tip was in a false passage above the diaphragm, as concluded at previous occasions. A grooved director inserted through that small opening repeatedly referred to, likewise, failed to meet the probe in the esophagus.

At about this time a peculiar tearing sound was heard, and the assistant who held the osteoplastic flap back with a pair of sharp retractors noticed that it had yielded considerably and could be lifted back much further than before. With the view of possibly overcoming the twisted course of the lower end of the esophagus, the stomach wall was grasped with several Muzeus's forceps around that small hole from within and pulled forward as we are wont to do with the bladder when extirpating a vesical tumor. But this proved to be a very disturbing factor in our work. The gastric mucosa being much thicker than that of the bladder, the teeth of the forceps had principally grasped the mucosa and, on continued traction, tore out one after the other, leaving persistently bleeding small tears, which blurred the picture in a most annoying way. The intention had at one time, to divide the stomach wall from within with Paquelin's cautery on a grooved director introduced through that small hole mentioned before, was given up again, on account of the result being too uncertain. This would have been the only chance for a successful issue of the task, according to my present view of the case.

In order to accomplish something in the way of helping the boy, if at all possible, a slender dressing forceps was now placed with its tip on that stellated scar, which had been regarded as probably representing the cardial orifice, pushed through the slightly resisting tissue and gently pressed upward for a distance of two to four inches. It was then opened and held in place. Through the opening thus made air was heard to pass in and out with each respiration. Various instruments were then pushed up, but all of them were arrested in their course at the same point, without touching the probe. Further attempts were thereupon abandoned. The new incision in the stomach was closed with a double row of Lembert silk sutures.

After the table had been lowered it was seen that much better access had been gained to the cardia than we had had in the beginning of the operation; the resistance of the flaps had evidently partially yielded to the continuous traction that had been applied. The cardia and immediate neighborhood of the stomach now were clearly visible and it was noticed, that by pulling on the stomach, the lower end of the esophagus could be pulled down. Had it not been for the precarious condition of the feeble patient, I should have at once made a second incision in the region immediately adjacent to the lower end of the esophagus and continued my efforts to carry my point. As it was, I had to give up all further attempts for the time being. The osteoplastic flap was fitted back in its former place, the skin being sutured with interrupted silkworm gut, without drainage. Recovery followed. Nutrient enemata were given for the first three days, when feeding through the gastric fistula was resumed. At present the patient is gaining about half a pound a week and, with careful nursing his general condition is steadily improving.[1]

It is needless to say that my inability to gain a passage through the esophagus from below was a great disappointment to me. I had hoped to see a silk thread pass from the gastric to the esophageal fistula at the end of the operation. Perhaps I should have been more successful had the osteoplastic flap yielded as fully in the beginning of the operation at it did toward the end. I should then probably have changed my plan and attacked the lower portion of the esophagus, with the patient on his back, and made an incision running directly up toward the region of the cardia.

As I do not believe that the boy, undeveloped as he is, will grow up properly under present conditions, it is my intention as soon as he has gained sufficient strength, to again raise the chest flap, open the stomach close to the cardia, follow up that blind canal mentioned above and try to find the way upward.

Surely this operation has shown me the great help we may expect from this osteoplastic raising of the lower part of the thorax, when it becomes necessary, to reach the ordinarily inaccessible organs situated in the convexity of the diaphragm.

It is my belief that gastrectomies, which hitherto may have appeared impracticable on account of insufficient access to the proximal end of the stomach, may now still be carried out by means of this osteoplastic operation. It further seems evident, that, by the help of this procedure, our surgical work within the vault of the diaphragm—on the left as well as on the right side—will gain considerably in exactness.

THE ETIOLOGY OF GASTRIC HEMORRHAGE.

BY F. GREGORY CONNELL, M.D.,

OF SALIDA, COL.;

ATTENDING SURGEON D. & R. G. R. R. HOSPITAL; CONSULTING SURGEON TO ST. VINCENT'S HOSPITAL, LEADVILLE.

Ulceration is the most common cause of hemorrhage from the stomach, but there are many other possible and probable conditions which may act as etiological factors.

So numerous are these different causes that they may be very conveniently designated as: (1) stomachic, (2) extra-stomachic, (3) unknown.

The conditions classed under *stomachic,* will

[1] Patient was presented before the New York Surgical Society on January 27, 1904.

include all those in which the primary cause of the hemorrhage is to be found in the stomach. With the hemorrhage due to *extra-stomachic* causes will be included, those in which the chief and primary cause is to be found in some of the adjacent structures; the gastric disturbance being but a secondary matter. Under the heading *unknown* will be classed the hemorrhages which cannot be accounted for pathologically.

In Stomachic Causes.—The frequency with which hemorrhage is detected in cases of stomach pathology, will depend to a very large extent upon the investigator, the more carefully it is looked for, the more frequently it will be found. The most frequent cause of gastric hemorrhage is ulcer of the stomach, which according to the most reliable authorities, occurs in about five per cent. of the entire population, though this percentage is questioned and severely criticised by Byron Bramwell.

Hematemesis, either chronic or acute, is present in from 45 to 80 per cent. of those afflicted with gastric ulcer. Leube found it in 46 per cent. of 556 cases, Ewald in 364 cases noted it 203 times, 54.5 per cent, while Greenough and Joslin discovered it in 81 per cent of 187 cases.

Ulcer and hemorrhage occur more frequetly in females than in males, and usually in the third decade of life.

Gastric ulcer may be described as a loss of substance of the stomach wall, "a progressive necrosis of tissue." The most usual form is the chronic, which may vary in size from 1 to 10 cm. in diameter. Its base may consist of any of the layers of the stomach wall, depending upon the destruction of tissue that has taken place. Its edges are terraced, involving more of the mucosa than the deeper structures, and are sometimes, but not always thickened, and indurated. In shape it generally resembles a shallow saucer, and may be either single or multiple. It is usually situated in the pyloric region, near the lesser curvature and most often on the posterior wall.

The acute form is similar to the chronic except that the deeper layers are as much involved as are the more superficial ones. Giving to the acute ulcer the "punched out" form described by Rokitansky, there is very little, if any, thickening, induration, or inflammatory reaction surrounding this type of ulceration. Hemorrhage or perforation may occur in either form.

The erosions of the stomach are closely related to ulceration, so closely, that some authorities consider them to be antecedents of ulcer, while others believe them to be separate and distinct lesions. They are small streaks, or rounded areas, from the size of a millet seed to that of a split pea, over which there is a loosening or a loss of the mucous membrane and on which is found extravasated blood, varying in color according to the stage of disintegration. Their number is variable, likewise their situation, though there seems to be a predilection for the region of the pylorus. Dieulafoy has divided these erosions into simple erosion, in which merely the surface epithelium is absent, and exulceration simplex, in which there is an extension to, and an involvement of the vessels which lie beneath the muscularis mucosa.

There are various theories advanced to explain the occurrence of ulceration of the stomach; such as an increase in the quantity or the quality, of the gastric juice, alkalinity of the blood, embolism or thrombosis, impoverishment of the blood, traumatism or irritation, spasm, nervous or trophic disturbances, omental adhesions, etc. But it may be said that the exact cause of ulcer of the stomach, if there is one, has not as yet been definitely determined.

Erosions are explained by the occurrence of an interference with the circulation of the superficial layers of the mucous membrane, which results in a hemorrhagic infiltration and digestion by the gastric juice, being practically the same as the embolic theory of gastric ulcer. Microscopically the ulcer will show but few changes of a marked character. Besides the loss of tissue, molecular changes in some cells, more or less round-cell infiltration and a proliferating endarteritis, there will be but little of note. The erosion shows, in the majority of cases, a loss of the superficial part of the mucosa, and, with the exception of an infiltration with red cells, there will be very little variation from the normal.

As the ulcer progresses, it involves numerous blood vessels; at first small ones, and then, as it invades the deeper structures of the wall, the larger vessels are eroded. Hemorrhage may be entirely lacking, or in such small amount as to be practically negative. Small hemorrhages may be repeated very frequently, or become practically continuous, resulting in very severe anemia. Larger hemorrhages may occur at intervals, or but once, and never be repeated, or may immediately terminate fatally. All this variety of hemorrhage from ulcers quite similar in character, and the fact that in one ulcer a large artery will be eroded with no hemorrhage, and that in another ulcer, comparatively small, involving only the smallest vessels, there will occur a hemorrhage so profuse as to cause death, has been explained by Ewald on the supposition that, in these cases, there exists a certain predisposition to a deficiency in the fibrinoplastic power of the blood, and with this an insufficient or ineffectual formation of thrombi.

Acute or chronic gastritis may, in aggravated cases, cause blood to appear in the vomitus, but a distinct hematemesis will but very rarely occur; as it may with tuberculous, typhoid, diphtheritic or other specific ulcerations of the gastric mucous membrane. The hematemesis caused by carcinoma, will usually be easily differentiated from that caused by ulcer, by means of the history, and the character of the vomitus, the "coffee-grounds vomit" of cancer. But in the early stages of carcinoma, and in the unusual case it will be impossible to differentiate, just as it is often im-

possible to differentiate by other signs or symptoms, or even by macroscopic examination. The fact that carcinoma develops from an ulcer in a certain proportion of cases, makes this differentiation more difficult and obscure.

Traumatism, direct or indirect, has been the cause of hemorrhage from the stomach in quite a few instances. And it should be remembered that hematemesis following a penetrating wound of the abdomen, does not necessarily imply that the stomach has been perforated. The accidental swallowing of foreign substances, such as pins, needles, tacks, etc., bones, glass, seeds, stones, or other materials in food and drink, may cause hemorrhage. Kocher mentions an instance in which hemorrhage was caused by the lodging of a cherry stone in an ulcer. Corrosive poisons, strong acids, alkalies or other irritants, such as drastic purges or emetics may excite bleeding.

Continuous vomiting or retching, the use of the stomach tube, or aspiration by the stomach pump, may injure the mucosa sufficiently to cause slight bleeding. Inflation of the stomach with CO_2 for diagnostic purposes has in one instance caused death, by exciting hemorrhage from the base of an ulcer. Another cause of gastric hemorrhage, to which attention has not been adequately attracted, is operation.

Instances in which operations of gastro-enterostomy, for benign stenosis of the pylorus, and gastrorrhaphy for perforation have been followed, after varying intervals, by hemorrhage from gastric or duodenal ulcers, have been reported by Furner, Collins, Eccles, White, W. Petersen, English, Keetley and others. Eccles, in explaining his case, says: "It is probable that the manipulation necessitated by the delivery of the stomach for operation, caused a fresh extension of the duodenal ulcer." Fatty, hyalin, amyloid or other degenerative changes of the vascular wall have been ascribed as causes in some few instances. Miliary aneurism has also been found to be the cause of hemorrhage. The swallowing of leeches, and the larvæ of insects, have been known to be followed by the vomiting of blood.

Extra-stomachic Causes.—The chief causative factor of hematemesis, outside of the stomach proper, will be found in various conditions, giving rise to interference with the portal circulation, as is best exemplified by cirrhosis of the liver. J. P. Frank, in 1794, was the first to observe the relationship of cause and effect, between cirrhosis of the liver and the vomiting of blood. Since then a number of most excellent articles have been written upon this phase of gastric hemorrhage. Law, in 1828, was one of the first to emphasize the subject. In 1884, Benz could find only 19 cases, but Debove, in 1890, and in 1900, Preble added so materially to the literature. Welch says, "Next to ulcer and cancer of the stomach, cirrhosis of the liver is the most frequent and important cause of gastrorrhagia."

Not alone cirrhosis, but any disease of the liver, such as syphilis, senile atrophy or portal thrombosis, capable of exerting pressure, or otherwise interfering with the portal vein or its subdivisions, may give rise to congestion of the gastric mucous membrane, and in turn to hematemesis. This variety of hematemesis, due to congestion of the mucosa, is not the common form, the more usual, 80 per cent. according to Preble, is the false gastrorrhagia, from esophageal varices. These esophageal varices form, at the esophageal, collateral portal circulation. Owing to the difficulty experienced by the portal blood in passing through the liver, numerous collateral circulations are established. One of these, at the esophageal opening of the stomach, where the gastric and esophageal veins anastomose, is frequently the site of great dilatation. Varices or esophageal "piles," as they have been called, are thus formed. These dilated and attenuated veins may rupture, and allow the escape of the blood into the stomach, from which it is vomited, causing a false hematemesis almost impossible to differentiate from the true.

Venous congestion may be caused by various other conditions such as enlargements of the spleen, or other intra-abdominal organs, adhesions to the stomach or other viscera. Causes of congestion other than interference with the abdominal circulation are less common. Interference with the thoracic circulation, as by emphysema, chronic pleurisy, fibroid lung, or by uncompensated cardiac lesions, may indirectly result in gastric congestion, and hemorrhage, but these are to be considered as very rare and exceptional, although not impossible, causes.

A simple perforating ulcer, *i.e.*, one perforating directly into the peritoneal cavity, comparatively seldom gives rise to hemorrhage. In Tinker's table of 76 cases of perforating gastric ulcer, details under the heading "Character of Attack" are given in 52 cases. In these 52 cases vomiting of blood was noted only five times. English found in 50 cases operated upon for perforation that hematemesis was mentioned eight time in the previous history (and twice it immediately preceded the perforation), but in ulcers perforating into adhesions or adjacent organs hemorrhage is much more common. The source of the blood may be very remote, and the course circuitous and obscure.

The rupture of the ventricle of the heart, an aneurism of the aorta, or some of its branches, a perigastric abscess or some similar condition, may possibly account for hemorrhage from the stomach.

Just what rôle is played by the central nervous system in exciting gastric hemorrhage, is not definitely known or settled. The intimate relationship of the stomach with the central nervous system by means of the pneumogastric nerves, as well as the communication with the sympathetic nervous system through the solar plexus, seems to make more plausible the theory

that some varieties of gastric pathology and hemorrhages may be directly due to lesions of the nervous system. Gastric hemorrhages have been noted in the source of epilepsy, tabes, hysteria, hydrophobia, tuberculous meningitis, progressive paralysis of the insane, and other nervous diseases. Nervous or emotional loss of balance are frequently followed by various manifestations of functional disturbances of the digestive mechanism.

One of the first cases in which a lesion of the central nervous system was demonstrated in hematemesis, was that of Dr. Brittan, reported by H. Bence Jones in 1860. A woman, aged twenty-nine years, had persistent stomach symptoms resembling those of ulcer. She twice vomited blood and died. At autopsy, all the viscera were found to be healthy, excepting a cyst in the fourth ventricle of the brain. Dr. Brittan concluded that irritation of the roots of the pneumogastric nerves by the cyst was the cause of the gastric symptoms.

Since then many similar cases have been reported and numerous experiments have been carried out with the object of ascertaining the exact relationship between lesions of the nervous system and abnormal conditions of the stomach wall, and as these conditions frequently give rise to hemorrhage, they will be of interest in this connection.

The experiments have consisted of such operations as cutting of the spinal cord (Koch and Ewald); intersection of thalami and cerebral peduncles (Schiff); destruction of the anterior corpora quadrigemina (Brown-Sèquard and Ebstein). Hemmeter observed submucous hemorrhages and small areas of necrosis in the stomach eight days after section of one or both vagi, in cats, dogs, guinea-pigs and rabbits. Saitta severed the vagus on both sides in sixteen rabbits and fed them on a weak solution of hydrochloric acid, and induced multiple ulceration with gastritis; in control animals with vagi intact, the procedure had no effect. Yzeren found that by dividing the vagi below the diaphragm that an ulcer was produced corresponding to those ocurring in the human stomach. The ulcer was usually situated in the pyloric region, close to the lesser curvature, and other regions of the stomach were not affected. The stomach became harder, which he supposed to be due to contraction, spasm, thus according with the theory of Talma. Fütterer has repeated many of these experiments, and calls attention to the difference between these artificial ulcers and those occurring in man. In the former healing is in progress, while, in the human stomach, there is no tendency to heal. It was only after destruction of a portion of the hemoglobin of the blood, that he was able to produce ulcers in animals that corresponded in both macroscopical and microscopical appearance, to those occurring in man.

As showing the present status of this theory as to the cause of gastric ulceration, we may quote from Welch: "Although ecchymosis in the mucous membrane of the stomach can be experimentally produced by injury of various parts of the brain and spinal cord, there is no proof that gastric hemorrhage which is of clinical importance is referable to structural diseases of the nervous system." And from Thoma, "As a matter of fact we find comparatively often in severe affections of the brain and the medulla oblongata, that there are numerous hemorrhages in the mucous membrane of the stomach and in the lungs. This is not very convincing proof, however, since a similar result is often seen in other diseases. All we can do in the mean time, is to accept the facts and ask further, whether the nerves are able to influence the permeability of the capillary wall."

III. Unknown Causes.—The occurrence of hematemetis, and the failure at autopsy to locate the site of the hemorrhage, has been the cause of considerable speculation and theorizing. Different terms have been used to signify this sort of hematemesis as, idiopathic, parenchymatous, capillary, hematemesis, analogous, active, constitutional. Watson, in 1832, expressed doubt as to the existence of this condition when he said, "Whether it be idiopathic, if indeed it ever be so." A different conception of the term is shown by Chomel, who, in 1841, said: "There are indeed cases, but in small number, where the hematemesis is evidently idiopathic. The complete return to health after such a hematemesis,, leads to the conclusion that it really was idiopathic."

Flint says: "Hemorrhages sometimes occur from the stomach, as from the bronchial tubes, the Schneiderian membrane, and in other situations, without any apparent pathological connections, neither following nor preceding any appreciable morbid conditions. It is then to be considered idiopathic." Welch tersely sums up the question when he said: "Whatever hypothesis one may construct from these so-called idiopathic hemorrages, the recognition of the clinical fact of their occurrence is important."

In recent years there is little, if any, more enlightenment upon this peculiar phase of the subject, than was given to us in 1842 by Audral when he said: "The blood accumulates in the vessels of some part of the mucous membrane and then escapes from them, and this is all we are able to discover."

As showing the circle within which investigations are frequently carried, a review of the explanations of these hemorrages will be instructive. In the early days as the escape of blood always followed the severing of an artery, it was reasoned that all hemorrhages followed the rupture of arteries. But Morgagni, in 1769, demonstrated by his dissections that the solution of the continuity of blood vessels was not a necessary antecedent for hemorrhage. Bichat, in 1799, propounded the so-called theory of

hemorrhage by exhalation, *i.e.*, the direct passage of the blood through the capillary wall. This was for many years accepted as the correct explanation of these cases by the foremost writers of their time, such as Watson, Tweedie, Goldie and others. But in 1865, Wm. Brinton, in a lecture upon disease of the stomach says: "In noticing the causes of gastric hemorrhages little need be said of the old doctrine of hemorrhage by "exhalation", through the coats of the vessels apart from any solution of their continuity. For we now know that the walls of even the finest capillaries have no pores of appreciable magnitude, such as would be necessary for the transit of blood corpuscles, and hence the extravasation of these structures is proof positive of some vessel having been ruptured. That among the myriads of these minute tubes present, the eye often fails to detect the exact vessel or vessels involved in the lesion, is of course not very surprising."

In 1867, Stricker and Cohnheim observed the passage of red blood corpuscles through the capillary wall and termed the process "diapedesis." Since then the possibility of diapedesis, as an explanation of these obscure cases has been accepted, but only after a most careful and painstaking examination of all the viscera has failed to reveal another cause.

At the end of 1903, Gerasimovitch cited a number of cases of hematemesis in which the only accountable causative factor was peritonitis. And upon a microscopical examination of the mucosa of the stomachs, minute hemorrhages by diapedesis were discovered. Welch, in this connection says: "Doubtless small gastric hemorrhages, particularly those into the tissues of the stomach, are often the result of diapedesis, but in case of profuse hemorrhages from the stomach, where the source of the hemorrhage is not demonstrated after death, the convenient assumption of hemorrhage by diapedesis, in my opinion, plays too important a rôle." He further states "that our knowledge of diapedesis does not warrant the belief that the red blood corpuscles can escape through the unsuffused walls of the vessels with the combined rapidity and abundance which would be necessary to explain the sudden and profuse hemorrhage."

It is the opinion of many that the origin of these so-called idiopathic hemorrhages, would be cleared up if a more careful examination were made. Ewald refers to the esophageal varices as an unsuspected and frequently undetected cause of hematemesis. Welch mentions a number of cases in which miliary aneurisms of the gastric arteries could have been easily overlooked. It is a significant fact, that cases of this variety appear to be decreasing in frequency, supposedly due to a more careful examination.

Dislike, as much as we may, to use the term *idiopathic* in this day and generation it must nevertheless be admitted that gastrorrhagia does undoubtedly occur, and at autopsy no rational explanation for the bleeding can be found. Such a case occurred under the master hand of Ewald in 1891. And similar ones have occurred in the experience of other experts. As showing the possibilities, in such obscure cases, that of John Mackintosh, published in 1837, will be interesting: A child died suddenly after vomiting a considerable quantity of blood. On dissection, the stomach was found filled with coagulum, and there was also some fluid blood in the small intestine. It was evident that there had been active hemorrhage, but after the most minute investigation, no blood vessel could be found from which it had issued. The contents of the thorax, including the great vessels, and the esophagus were dissected out, and examined at leisure. It was then discovered that the blood found in the stomach and bowel had proceeded from a ruptured artery in a cavern in the superior lobe of the left lung. A fistulous opening connected this cavity with the esophagus through which the blood passed into the stomach.

Hemorrhages from the stomach occur occasionally during the course of different diseases, such as typhoid, typhus or yellow fevers, cholera, measles or scarlet fever. Such hemorrhages are explained in various more or less satisfactory ways, such as the presence of bacteria in the blood, the breaking up of the corpuscular elements of the blood, or changes in the vascular wall owing to the alteration of the blood by toxins or otherwise. But it may be stated that the cause of gastric hemorrhages in such general diseases is not understood.

Melena neonatorum; gastric or duodenal hemorrhage sometimes accompanied by hematemesis, in the newly born, is likewise due to unknown causes.

A strong and unexpected shock of electricity to the epigastrium has been known to be followed by profuse hematemesis leading to death. No autopsy was performed.

Under this heading, unknown causes, must be included the so-called vicarious menstruation, and postoperative hematemesis. Many examples of vicarious menstruation will be found in the literature, cases in which, for some reason or other, the menses cease to flow, and in place of which, there occurs a vomiting of blood. Similar compensatory hematemesis are said to occur, in place of an interrupted, periodic epistaxis, or hemorrhoidal flow. The existence of such conditions are denied by many, but the majority of authorities seem to acknowledge such possibilities and their very rare occurrence. English found hematemesis undoubtedly more frequent before the onset of menstruation, which he explained by the high blood-pressure, at that time.

Postoperative hematemesis must be divided into three varieties: (1) Hematemesis, following stomach surgery, due to imperfect suturing or hemostasis. Such a hemorrhage will be con-

sidered as secondary. It must be remembered that the gastric mucosa, on account of its abundant blood supply, is liable to bleed freely after operation, unless a continuous suture is employed. (2) Hematemesis, following stomach surgery, due to interference with a pre-existing and unsuspected ulcer. Such cases are extremely rare but a few have been reported thus far, and have been referred to as traumatic causes of hemorrhage.

Neither of the above are what is commonly understood by "postoperative hematemesis." As ordinarily used it is intended to signify the vomiting of blood following operations upon adjacent viscera, but in which the stomach is not involved.

This is a newly described condition and Rodman, in his oration on surgery at the 1900 meeting of the American Medical Association, was one of the first in this country to call attention to it, although Robson, in England, and Von Elsberg and Dieulafoy on the Continent, had already described cases. Seven cases in the experience of the former, and six and seven by the other two, comprised practically all the published cases, at that time. Rodman, by means of letters of inquiry to fifty representative surgeons of America, learned that only eleven cases had been encountered, and these by nine of the men interrogated.

Since then, many additional instances have been reported. Its occurrence in connection with the operation for appendicitis has excited considerable comment and controversy. Post-operative hematemesis has followed a great variety of abdominal operations such as appendicitis, hernias, operations on the liver, gall-bladder or ducts, the opening of abdominal abscesses, hysterectomy, operations on the kidney, ovarian cysts or tumors, extra-uterine pregnancy, ligature of omentum, etc. It also has been known to follow extra-abdominal operations.

Among the various explanations of the occurrence of vomiting of this character are theories of sepsis, embolism, interference with vasomotor control, changes in the blood caused by the absorption of bile, in gall-duct or liver cases, administration of chloroform or manipulation or traumatism of the viscera, especially the omentum. The use of the Trendelenburg position has been presented as a cause.

Rodman made a few experiments upon dogs, in an endeavor to find the exact cause of these hemorrhages, but was unsuccessful, and in his conclusion attributes them to septic conditions which favor the disintegration of the blood corpuscles and predisposes to hemorrhages from the mucous surfaces. He says: "We have in this, I think, a satisfactory explanation of the rare hematemesis following abdominal operations, and have shown that even violent traumatism to the omentum, intestine, spleen, pancreas and liver, did not produce hemorrhage into the stomach in any of the dogs experimented upon and it does not seem unreasonable to suppose that delayed hematemesis will usually depend upon disintegration of the blood due to sepsis." Gerassimowitch in a very recent contribution upon this subject, arrives at practically the same conclusion. He considers the hemorrhage to be due to toxic changes in the blood vessel wall, with a vasomotor paralysis, a local stasis, and a rise of blood pressure, all of which is usually caused by a septic peritonitis.

The exact cause of postoperative hematemesis is very much in doubt, and a question upon which there is need of a great deal more study, before an accurate understanding will be reached.

A SERIES OF NEARLY SIX HUNDRED SPASMS IN AN EPILEPTIC WITHOUT DISTURBANCE OF CONSCIOUSNESS IN THE INTERVALS.

BY L. NEWMARK, M.D.,
OF SAN FRANCISCO, CAL.

A WOMAN, whom I have known as an epileptic since November, 1894, had her first fit in October, 1892, when she was twenty-four years old. A witness of this and other seizures, says that after the attack, she was demonstratively and indiscriminately affectionate and was confused for about an hour. After this first fit she is reported to have slept almost continuously for two or three days. This postparoxysmal behavior is noteworthy, for while it was common in some degree or other up to the time of the numerous series to be hereinafter described, it was not a feature of the latter.

Many of the fits began with flexion of the forearm, which was followed by a turning of the head and eyes to the left. Of the first or both of these movements, the patient was often conscious; she would then lose her senses and the jerking of the limbs became general. The tongue was bitten in some of the seizures, in others the lower lip or the cheek. She might be warned by a vague nervous feeling in time to seek a couch, or be overcome by the attack without a warning and injure herself in her fall. The fits ocurred at various times of the day or night, as many as five in a single night.

The removal of one of her ovaries in February, 1894, by a gynecologist who alleged that it had undergone cystic degeneration, had no effect whatever on the disease. Bromide of strontium which I prescribed, influenced the frequency of the seizures, but did not suppress them altogether. Under the influence of this drug, the daily dose of which had gradually been increased to seven and a half grams, as long an interval as nine months was achieved between fits. Suspension of the bromide was often promptly followed by a fit, and a diminution of the dose also increased the liability to an attack, so that the patient finally refused to restrict the amount to less than the quantity mentioned. She was disfigured by the acne and her nutrition seemed considerably impaired.

Therefore, when bromipin was introduced, it was hoped that it might have the advantages of bromide without the drawbacks. Accordingly it was substituted for the salt on the first day of June, 1901. At first the dose administered was three teaspoonfuls daily. Seizures ocurring on June 7 and on June 22 and 25, and again on July 24. The dose was gradually increased to three tablespoonfuls daily. To the nervousness and insomnia caused by the change from the bromide to the bromipin, was now added great vexation by her discovery that she was pregnant for the second time. Her tendency to convulsions seemed to be culminating when her husband reported to me that in the night from July 28 to 29 she had had nine seizures, after each of which she was immediately conscious. Such an accumulation of seizures surpassed all her previous experiences, but this was only the prelude to a protracted spectacle.

At noon on July 29 I visited the patient at her residence in the country, about twenty miles from town. I found nothing abnormal in her condition except a slight elevation of temperature (99.8° F.). The resumption of her former dose of bromide was ordered, besides three grams of paraldehyde at night. At a quarter to two in the morning of July 30 the fits began again, and by four o'clock in the afternoon 47 of them had ocurred. They varied in duration between forty-five seconds and two minutes. The second fit followed fifty minutes after the first. Five minutes was the shortest interval noted, and commonly fifteen minutes passed between them. The patient felt a premonitory tingling in the left hand from the tips of the fingers to the wrist. A shriek often announced the fit, which began with a turning of the head and eyes to the left; then there was tonic flexion of the left wrist and elbow, the arm rising somewhat at the shoulder, and the left side of the face contracting. The left lower extremity was extended, the foot turned plantarward and pointed inward.

This tonic stage was followed by violent clonic contractions of the left facial muscles, in which, however, the eyelids on both sides participated, and of the muscles of the left upper extremity, while in the left lower limb only a rapid quivering of the muscles was observed. The right limbs were generally not affected at this time; at the most they were involved in a slight degree in the tonic contraction. As soon as the convulsion ceased, consciousness was found to be undisturbed and the patient denied that it had been altered at all during the seizures.

After the tenth attack she complained of a "limp" feeling in the left arm. Later, both extremities became powerless after the fits, power returning more or less according to the duration of the intervals, to be lost again after a fit, until late in the afternoon a flaccid paralysis of the left limbs became well established. Sensation of all kinds in the paralyzed limbs was perfect. The knee-jerks and ankle-jerks were equal on the two sides and were easily obtained. The same was true of the reflexes in the upper limbs. There was no headache. I was present when the patient ate her supper in the evening of the first day after a severe fit in which the right limbs also jerked somewhat. In the intervals there were often slight spasmodic movements consisting in tonic flection of the left fingers or wrist or (more rarely) of the elbow.

Between four o'cleck in the afternoon of July 30 and the same hour of July 31 the fits numbered 87. The right limbs and the right facial muscles were now involved in the spasms as well as the left, and the patient became deprived of motion in all four limbs. Convulsions, from now on bilateral, followed one another somewhat more rapidly than before, the most rapid succession being after one and after three minutes. After the one hundred and nineteenth seizure, the hypnotics and narcotics and other measures having been unavailing, I gave orders to chloroform her. She was kept under the influence of the chloroform for one hour; forty minutes after its withdrawal the one hundred and twentieth fit was added to the series.

In the twenty-four hours ending at 4 P.M., on August 1, eighty-eight attacks were registered. Between the one hundred and fifty-fourth and one hundred and fifty-fifth a pause of 55 minutes afforded some encouragement, but 90 attacks in the next period of twenty-four hours and 96 in still another, permitted no prediction as to the exhaustion of the discharging material. Between corresponding hours of August 3 and 4 the maximum of frequency was reached, 111 seizures having been recorded in the twenty-four hours.

Her condition had now become most deplorable. As has been said, the limbs were motionless; later with the multiplication of attacks she lost power over the movements of the head and when she was lifted the head wobbled. Then her speech become thick. The indistictness of her articulation increased gradually until at length, not being able to utter the whole words intelligibly, she would laboriously spell them. Finally, on August 4, she could not even raise her eye-lids, the act of swallowing grew more and more difficult, then altogether impossible and she had to be fed by the rectum. At last she lay motionless and speechless, her inertness being interrupted only by the spasms. The limbs were relaxed and remained as the convulsions left them; for instance, the forefingers extended, from pressure of the adducted thumbs against them, while the other fingers preserved the position of interosseal flexion.

Seizures followed one another fast and furiously, as many as five occurring in thirteen minutes; but longer intervals were also observed, as many as fifty and sixty-nine minutes elapsing without an attack. For a time a series of three or four or five attacks in very rapid sequence

would alternate with a relatively long pause so regularly that the course of events was in a measure predictable.

On August 5, in the morning, several intervals of over an hour indicated a lessening of the convulsive tendency. By ten o'clock in the forenoon 54 fits had been counted since the last reckoning at 4 o'clock in the afternoon of the day before: then there were no more until five minutes to six in the evening when the five hundred and seventy-fourth convulsion closed the series.

In the bilateral fits the movements of the left upper extremity generally preceded those of the right a little. Head and eyes invariably turned to the left at the commencement of the tonic stage, the mouth opened, the facial muscles underwent tonic contraction; usually the upper extremities were extended and slightly abducted, the forearms pronated, the wrists flexed, the thumbs without exception turned in and caught between the index and middle finger, while the other fingers were flexed in the metacarpophalangeal joints. The abdominal muscles were also rigid in the tonic stage. The lower limbs were extended and the feet flexed plantarward and turned in. There was nothing faintly resembling the "*arc de cercle.*" The brief tonic phase was followed by clonic contractions in the face and in the upper extremities, succeeding one another at first rapidly, then after longer pauses. The last contraction in the upper limbs equalled in violence the former ones, so that the spasm of these limbs ended with a fling. The twitchings in the nether extremities were quick, short, almost tremor-like. A cork was inserted between the teeth at the approach of a fit; nevertheless the lower lip and the mucosa of the cheek were often bitten and the tongue twice, once quite deeply on the right side. At the close of the clonic spasms the patient emitted a snoring or snorting noise and foamed at the mouth.

The pupils dilated at the onset of an attack. In the intervals they were narrow, but reacted distinctly, until August 4, when reaction to light was hard to determine, clearly because of the tendency to roll the eye-balls upward. On August 2, with a strong endeavor she succeeded once in moving the right big toe and the left forefinger. After her articulation had become difficult a great effort would now and then produce a short, plain utterance, as when at the approach of a fit she called out to some one: "Get off the bed." At no time could a plantar reflex be obtained. From July 30 on, the ankle-jerks and radius and elbow-jerks were very faint, while the knee-jerks in the interval between fits remained brisk. But when the knee-jerks were tested immediately after the fits, that is to say, as soon as the limbs were relaxed, they were found to be absent for about one-half to one minute, and gradually regained their vigor. Sensation, the optic disks, and the urine presented nothing abnormal. In some of the later attacks urine or feces was passed involuntarily. The temperature did not rise above 101° F.; the pulse-rate was rapid, 120 to 140 much of the time, owing, no doubt, to the agitation of the convulsions.

While the attacks were unilateral it was not surprising that they did not affect the mental condition; but the absence of any affection of consciousness or of the intellectual or emotional state, after the body had been racked by hundreds of bilateral convulsions, impressed the observers as something extraordinary, one of them at least to the extent of making him doubt the epileptic nature of the seizures. Even after the most protracted of all the fits, the three hundred and seventy-fourth, which is stated in the nurse's record to have lasted four minutes and which was probably one of those in which the patient bit her tongue, the very vigilant nurse did not observe any delay in the manifestation of consciousness.

Sleep occurred normally or was induced by hypnotics. It was very frequently interrupted by the convulsions, after which the patient was fully awake, and it could at no time be mistaken for an epileptic torpor.

Before the last fit of the series had occurred the power of swallowing had returned in a good measure. The recovery of speech followed. By August 6 she could move the lower limbs and had a good grip with the right hand. As late as August 11 the movements of the left hand were awkward and when the left forefinger was to touch the point of the nose it went wide of the mark. The stereognostic sense was preserved. The right hand had gone through a similar disturbance before it completely recovered. All functions were finally restored. On November 22 the patient had a fit of the kind that prevailed before the series and since then she has been having a few of them in the course of a year, living under the protection of bromide.

To readers of the recent works of L. Pierce Clark and Spratling the foregoing will present nothing new. But to the general medical reader it may be offered as illustrating how multitudinous seizures may fail to impair consciousness in a disease in which the individual attack is usually attended with its disturbance or loss, as exemplifying in a remarkable degree the exhaustion paralysis of epilepsy, and as a warning of the danger which may arise from too rapid a diminution of the sedative control exercised over the epileptic brain by bromide.

Unionism in Medicine.—At a meeting of the Physicians' Club, held October 20, this subject was discussed by several physicians and laymen. Dr. Alfred C. Croftan believes in a united profession, but not in a unionized one. Dr. George F. Butler said the labor unions believed in high wages for their members, but patronized advertising charlatans and encouraged cheap and unskilled labor in the medical profession. The principal objection to the union idea was that it implied the regulation of prices, while nearly all the practitioners who spoke agreed that they were in the profession solely for the benefit of humanity.

THE AGNES MEMORIAL SANATORIUM.

A DESCRIPTION OF A SANATORIUM FOR THE TREATMENT OF PULMONARY TUBERCULOSIS, BUILT BY MR. L. C. PHIPPS, AT DENVER, COL.

BY CARROLL E. EDSON, A.M., M.D.,
AND
W. H. BERGTOLD, M.SC., M.D.,
OF DENVER, COL.

The Agnes Memorial Sanatorium has been erected at Denver, Col., by Mr. Lawrence C. Phipps, of Pittsburg, as a memorial to his mother. An attempt has been made to have it in every detail the most thoroughly built and equipped institution possible, and Mr. Phipps has spared no expense to this end. An account of the plans and construction of the sanatorium may therefore be of interest. Mr. Phipps having determined upon building for this memorial a sanatorium for the care of persons of small resources suffering from pulmonary tuberculosis, purchased a large tract of land in the suburbs of Denver. In April, 1902, he laid his plans before the gentlemen whom he later asked to be the trustees of the sanatorium, which is incorporated under the laws

Fig. 1.

General View.

of Colorado as a permanent charity, and before the physicians whom he had selected for his medical board.

The members of the medical board, being asked to make all necessary suggestions as to the details and requirements of such a sanatorium, gave their enthusiastic attention to this work and recommended: That the institution be conducted as a closed sanatorium for the open-air treatment of persons of small means suffering from incipient pulmonary tuberculosis; that it be, not a home or refuge, but restricted to cases of early disease in persons whose return to wage-earning is urgent, and whose condition offers prospect of such arrest of disease or amelioration within a short period as to permit of such return; that the institution should be planned to give such persons, for a period of six months or so, the very best opportunity for outdoor living, physical quiet, abundant nourishment and medical oversight at a small cost; that the sanatorium also be not only therapeutic, but educational, the patients being taught how to take proper care of themselves after leaving.

After long and careful consideration, the medical board reported, on November 14, 1902, to Mr. Phipps detailed suggestions and specifications as to the arrangement and construction of the buildings. These recommendations have been closely followed in the main, Mr. Phipps making from time to time some changes in the way of addition to the simpler ideas of the board, but in no way affecting the general plan as first laid down. The specifications were given to the architects, Messrs. Gove & Walsh, of Denver, in November, 1902. These gentlemen have in every way most cordially cooperated with the medical board, and subordinated their architectual ideals at all times to the medical demands.

During the winter of 1902-3, the detailed plans were worked out by the architects and physicians with great minuteness, and ground was broken in May, 1903.

The erection of the buildings since then has been under the direction and in the hands of the building committee of the board of trustees, which was organized in January of that year.

The land comprises forty acres, upon high ground, seven miles east of the city of Denver, and well situated so as to be wholly free from smoke or future crowding. One hundred and twenty acres additional to the east and south are owned by Mr. Phipps, and while at present used as a ranch in connection with the sanatorium, may be drawn upon for future needs. The site is on the line of the electric cars, giving easy access from the city, and the elevated ground commands an uninterrupted view of the mountain range to the west—one hundred and fifty miles from Pike's Peak to Long's Peak, and of the plains to the east. The view from the tower of the administration building extends over more territory than the entire State of Massachusetts. The land slopes gently to the east, south and west, and is the usual prairie oversoil with a gravelly subsoil giving good drainage. The water supply is ample, furnished by the excellent city water of Denver, and by an artesian well 750 feet deep, upon the grounds.

It was decided for reasons of economy in administration, especially of ease of heating in winter, to adopt the pavilion system at first, and to increase the capacity, if desired later, by the erection of cottages from time to time. The buildings are now planned to accommodate eighty patients; the administration plant, kitchen, etc., being arranged for an increase to one hundred and fifty patients, which is considered the maximum number desirable under one control.

There are at present five buildings—an administration house, two pavilions for patients, a medical building and a power and laundry plant. The main buildings are in a line, the administration building between the two pavilions and a little behind them, while the medical building is to the north of the north pavilion. The power plant is 300 feet east of the rear of the main building.

The orientation was most carefully considered

in regard to sun and wind, both the prevailing and the storm wind, and in view of the needs of both winter and summer life. The buildings face west-southwest, save the medical building which is squarely on the compass. This arrangement was expected, as it has been found to do, to give every room direct sunlight every day in the year, and to provide sunlight on the verandas of the pavilions all day in winter, and in summer shade from the warm Colorado sun. The working out of this arrangement took much time, but has been very successful, as will be shown in the detailed description of the sleeping pavilions.

The buildings are all of brick, covered with cement, and roofed with red tiles, the general effect being that of the Spanish Mission so well suited to the western sun and landscape. The buildings are all connected by open cloisters, and below ground by a dry, well-lighted subway for use in administration work or very stormy weather. There is a full cemented and plastered cellar under every building.

The lighting is by electricity, generated in the

Fig. 2.

Administration Building, showing Sun Rooms and Open Cloister.

power plant, and the heating is the "direct-indirect" system of air over steam coils, to be described in connection with the pavilions. In addition, all rooms used for general assembling have open fireplaces.

The Administration Building, in the center, is 139 by 40 feet, and three stories high, with a two-story ell 51 feet deep. It contains the offices, the library, parlors and dining-room for the patients, the kitchen and pantries, and the living apartments for all the employees, from the Medical Director down.

The cloister connecting the pavilions runs directly in front of the main building and is here shut off by glass doors to make a vestibule. Entering the center hall, the dining-room, 60 by 40 feet, is on the right, where it has the full benefit of the morning sun on the east and south, the afternoon sun being to some extent shaded by the cloister on the west side. On the left are two reception rooms, 15 by 18 feet, in which patients may meet their callers, it being the intention to allow no visiting in the sleeping pavilions. Across the side hall on the east from the reception rooms are the office for the clerk, where patients will transact their business and receive mail, and the private office of the executive superintendent. The clerk's office opens also by a door to the rear of the building, giving easy access for delivery men to present bills of lading, etc., or for outdoor employees to do business without coming through the house. The north end of the first floor is given to the library, 20 by 40 feet. In the rear wing are the superintendent's family dining-room, the sewing-rooms, kitchen, pantries, refrigerator rooms and a dining-room and sitting-room for the servants. In the basement of this wing are the vegetable cellars, bake-ovens for bread, and the storerooms, entered from outside on the north.

The second floor is occupied on the north wing by the superintendent's and house physicians' rooms, on the south wing by the linen-rooms, sewing-rooms and quarters for the matron, housekeeper and nurses. In the second story of the rear wing are sleeping rooms for the servants, the necessary attempt at separation of the sexes being made by dividing the corridor by a solid wall, so that the women's rooms are wholly apart from the men's.

The third story of the main building was added for architectural effect, and advantage was taken to use the south end for an assembly hall, 40 by 60 feet. This room is one and one-half stories high, the ceiling being vaulted to the roof—the double row of windows and dormers giving ample ventilation. It will serve for occasional lectures and concerts. Objection may be made to this room being on the third floor, but the stairs throughout the sanatorium are of very easy rise and tread, and a patient unable to go up to the hall ought not to be at any entertainment.

The north end of the third floor gives extra room for an increase in the number of employees.

In front of the administration building, separated from it by the cloister, are two large sun-rooms, 38 by 24 feet, for use in severe cold or occasional hard storms in winter when a porch is too exposed. The sides are wholly of glass in French windows, and the rooms are shut from the open cloisters by glass folding doors. The rooms are thus open on all sides to light and sun, while they may be protected from the wind wholly or on any side as may be needed. They are amply ventilated aside from the window openings.

The cloisters running between all the buildings are covered passages with wide open arches of seven feet span. The piers are less than three feet wide. Throughout, these cloisters are wholly open, giving free circulation of air. The purpose of the medical board, throughout all the construction, was to do away as far as possible with confining walls, and to secure the greatest abundance of light and air, at all times. In case of severe storm, the corridors under the cloisters

may be used by the more delicate patients in passing from the pavilions to the dining-room. These passages are dry and well lighted, and serve to carry the steam, water and wire pipes.

The Pavilions, which are the essential working parts of the institution, are on either side of the main building, 70 feet distant each, and 50 feet in advance. They are 160 by 65 feet, counterparts, each two stories high, the upper story in all details like the lower. Each pavilion accommodates forty patients.

The bedrooms are all of the same size and arrangement; 11 feet wide by 16 feet deep, a closet three feet deep being taken off at one side of the inner end, making the main room 11 by 13 feet. All the rooms are 11 feet high. Over the door leading to the ante-hall is a transom serving to light the corridor, which is 8 feet wide, and to allow cross airing if wanted. Opposite this door is a window 38 by 78 inches, and next the window a door opens on to the veranda. This door is glassed, and is 4 by 7 feet, with a glass

Fig. 3.

Pavilion (north).

light above, 41 by 20 inches, so that, practically, the whole veranda end of the room is window, admitting abundant sunlight, which strikes completely across the floor of every room at some time during the day.

It will be noticed on the plan that the window of each room is opposite the inner door and transom, permitting full airing across the room, but leaving the bed, which stands opposite the outer door, out of the draft, also, that the doors of rooms across the hall are not directly opposite each other, which prevents an undue directness of draft and gives better general ventilation through the hall. This ample means of airing the rooms is, however, only supplementary, the system of heating and ventilation securing a supply of 10,000 cubic feet of air per hour, without the use of door or window. This is obtained by means of the direct-indirect system, so-called, of intake, separate for each room, allows the fresh outside air to pass over through a steam coil boxed under the window inside, and so up into the room. On the side wall, near the base board, is a ventilating register which opens to a flue passing separately for each room to the attic floor, where these flues open into a large shaft around a steam drum. The air suction is steady and sufficient to ventilate the rooms thoroughly and continuously.

The rooms are lighted by electricity, and the closet by globes automatically lighted when its door is opened.

Each floor has a lavatory suite, on the east side at the end nearest the administration building, which is tiled throughout with white porcelain. There are in each suite three tubs, a shower and a sitz-bath, and three water-closet seats, each in a separate room. A chambermaids' workroom, also tiled, and small linen closet complete the equipment on each floor.

The plumbing throughout the whole plant is open and exposed.

The stairways are in the middle of the east side, and are of very easy ascent, the rise and tread being 6½ and 12 inches, respectively. The floors throughout are of hard pine, filled and waterproofed, and the ceilings and walls are finished with a washable surface. All corners and angles in the building are rounded and concaved in the plastering. The dividing walls are double, and made sound-proof by zigzag felting. The bed spaces in adjoining rooms are never against a common wall.

The special feature of importance, however, in the pavilions is the veranda which surrounds the building on all sides. These verandas are nine feet wide, and are intended to serve as sleeping porches at night as well as piazzas by day. The arches, which carry the roof of the building and, therefore, appear structurally as if the outside wall, are very wide and cut clear to the ceiling. The arch space is 12 feet, and the intervening column is but eight inches in diameter. Its corners are cut away, as well as the outer edges of all the arches, so that the least possible obstruction is put in the way of sunlight. The columns, too, it will be noticed, are placed opposite the intervening walls between rooms, so that the whole of every window and door is directly behind the full opening of an archway. In this way no obstruction of light or air is given any room.

A canvas partition is fastened to the wall between each two rooms, and at night is drawn out to the column between the arches, dividing the veranda into porches, 12 by 9 feet; one for each room, giving privacy for the patients, whose beds are rolled from the room through the wide door out upon the veranda. The canvas screens are only eight feet high, so that there is free circulation of air above them along the veranda. Not only do these porches serve as sleeping spaces at night, but should any patient be obliged to keep his bed for a few days for any reason, the screens may be drawn out separating his porch from the general veranda, giving quiet and isolation and permitting him nevertheless to have his outdoor life uninterrupted. The screens may also serve

as partial wind breaks, in case of heavy wind down the veranda, though this protection is secured by the tower corners. At each corner of the pavilion, the veranda is widened two feet into the tower, the arches here are fitted with glass doors, which can be closed, giving a sheltered corner room 11 feet square, open on the two inner sides. These closed corners serve well to shut off the wind down the verandas.

Save in the most rigorous weather for a few nights in the winter, patients may thus sleep out all the year round.

The south end porches on which no rooms open give very sunny sitting places in winter, while the north ends similarly arranged give shady spaces in summer. As the patients here will not go away in the sumer, it was important to provide not only for sun and shelter in winter, but also for shade and coolness from the warmth of the summer midday. The time spent in planning this orientation was well repaid by the working results obtained.

The objection made to verandas around buildings, or in front of sleeping rooms, in most essays upon sanatorium construction, was not unnoticed by the medical board in planning these pavilions. In the intense sunlight of the unclouded sky in Colorado shade is desirable for some patients at all times, and for all during the midday in summer. The diffusion of light being so great, directness is less constantly needed, but it has been found that the porches about the pavilions do not shade the rooms at all too much. The direct sunlight strikes clear across every room at some time in the day. During the winter, the lower sun pours straight into the verandas all day, while in summer it is high enough so that the porches are shady save in the morning and evening.

Fig. 4.

Medical Building—Cloister and Pavilion.

The furniture of each room is simple and, so far as possible, without anything to catch dust; it consists of an enamel bed, which can be rolled through the doors upon the porch, an enamel washstand, a dresser, a small table and a chair. The floors are bare but for a small rug at the bedside. A call bell communicating with the nurses' room and light-button are at the head of the bed, and on the veranda a drop wire gives opportunity for light in each porch section in case of need when the patient is sleeping out. During most of the time, the bedroom will really serve only as a comfortable dressing room.

The Medical Building, which faces on the four points of the compass, is at an angle with the north pavilion, and thus falls back out of view in the full face of the general plan. It serves for the scientific work of the institution and for a hospital for any cases of acute illness which may arise and call for special nursing. It is 50 by 57 feet. The first floor is given to the scientific work. A reception room, 15 by 17 feet, is entered from the hall on the left. This opens into the consultation room, 30 by 15 feet, where the physicians have their desks, records and library. From this room opens along the north side of the building, a series of rooms: First, a small, quiet room for chest and physical examinations, then a room for throat treatment, and, lastly, on the northeast corner, a clinical laboratory, 18 by 15 feet. These rooms can be entered each from the hall or directly from each other. The throat and chest rooms were made separate from the consultation room to allow undisturbed examination or treatment of two patients at the same time.

Fig. 5.

Sleeping Porch.
At time of taking photograph the canvas partitions were not in place.

The clinical laboratory has a large north window for microscopical work, sinks and chemical hoods, and is thoroughly equipped with every appliance for scientific clinical work. In connection with the laboratory, there is in the basement a large, well-ventilated room for experimental work on pigs or rabbits, and a small autopsy room, which, it is hoped, may never be used.

A room arranged for X-ray work and a commodious dark room for photographic work, fill the eastern side of the building, and a small drug room for medicines and supplies completes the first floor.

A stairway made especially wide for carrying

a stretcher leads to the second floor, which is for hospital uses. A small diet kitchen, a small operating room, sufficient for such emergency work as may arise, are on the north side. A commodious bathroom is fitted with a tub in the center of the room for convenience of the nurse getting at the patient. There are six rooms, 11 by 15 feet, for patients, one being arranged for isolation in case of need. On the south side, built out over the cloister, is a large sun room for semi-convalescent patients, and the roof of the cloister beyond offers a still more open place for reclining when returning strength permits.

The power plant is 300 feet from the rear of the main building. It is 113 by 40 feet, with an ell 59 by 28 for the laundry. The main building contains the boilers and steam plant, electric generating dynamos, fire pumps and refrigerating machine. The laundry room is equipped with modern machinery, all the laundry material being sterilized by steam before delivery to the laundry room proper. The chimney stack is 100 feet high.

In connection with this building is an incinerating furnace for sputum and garbage.

The drainage of the institution is carried for the present, as the city sewers do not yet extend to the site of the sanatorium, to the east of the buildings in two sets of three series of settling cess-pools, which are dug deep into the loose gravel, draining away from the institution. The outflow is ample, as proved by tests.

APPENDIX I.

The Report of the Medical Board, made November 14, 1902, upon which the plans were drawn:

The Medical Committee, appointed by Mr. L. C. Phipps, October 27, 1902, to examine the plans presented, and to make all necessary suggestions as to the requirements of a sanatorium for tubercular patients, respectfully submit the following suggestions:

1. That the institution be considered a "closed sanatorium," non-sectarian, admitting both sexes.

2. That a uniform rate be charged, this rate to include board, lodging, and ordinary medical attendance, but not to include medicines, laundry, special operative work or special nursing.

3. That the sanatorium in no sense be considered a "consumptives' home," in the ordinary acceptance of the term. It should be an institution where patients with slight disease (incipient cases), can be sent with a hope of cure, or of such amelioration of symptoms that they may become wage earners again.

4. That it be, moreover, an educational institution where the patients are taught the simple but important laws of hygienic living, with special reference to their disease and the protection of others.

5. That the sanatorium be for the open-air treatment of patients, that every part should be extremely well and independently ventilated, readily cleansible without raising dust, as regards the patients' quarters, freely open to the sunshine, while sheltered from the wind.

6. That the sanatorium be built on the "pavilion plan," with an annexed "cottage system" later if deemed desirable."

7. That the first buildings be planned to accommodate not over eighty patients, forty to each two-story pavilion, the upper floor of one pavilion to be devoted exclusively to women, namely, 20. The maximum capacity of dining-room and kitchen to be built for the accommodation of 125 patients.

8. The Committee would advise that the sanatorium include the following buildings: (1) One administration building, (2) two pavilions, (3) medical building, (4) infirmary, (5) building for laundry, lighting, and heating plants, (6) amusement pavilion, (7) medical director's residence, (8) stable, (9) cottages when required.

9. The Administration Building should have the following rooms: *First Floor.*—Two reception rooms, one general dining-room, staff dining-room, superintendent's office, clerk's office, library, serving-room, kitchen. Cold storage for meats, vegetables, milk, butter. Small dining-room for help. *Second Floor.*—One matron's sitting-room, one matron's sleeping-room, one linen and sewing-room, one superintendent's room, nurses' rooms, rooms for superior help.

10. *Pavilions.*—The main front of the pavilions should face southwest. Each pavilion should not be over two stories high, with covered verandas on each floor around entire building; each floor to have sleeping rooms for twenty patients; each floor to have a bathroom containing three bathtubs and bowls, three seats, two urinals and one sitz-bath; each floor to have a closet for slop-hopper, with hot and cold water; each floor to have a linen closet, etc.; each floor to have a closet for soiled linen basket; each floor to have provision for collecting sputum cups; each floor to have a closet for brooms or mops; each pavilion to be provided with corridors not less than nine feet wide, amply lighted and ventilated.

11. *Medical Building—First Floor.*—One reception room for patients (to have double doors between reception and consultation rooms); one consultation room, with doors like the preceding; one chest examination room; one closet for washbowl, one nose and throat room, one X-ray and photographic room, one clinical laboratory, and one drug room (both to have running water). *Second Floor.*—One house medical officers' sleeping-rooms, house medical officers' sitting-rooms; extra bedrooms for visiting physicians, one toilet room with bath, and seat.

12. *Hospital Building—One Story.*—One nurses' room, one reception room, ten sleeping rooms, to open on covered veranda, one to be arranged for isolation room; one toilet room, with bath, bowl and seat; one diet kitchen, one linen closet, one closet for slop-hopper and cleaning rags, one operating room (small), one mortuary in basement.

13. *Amusement Pavilion.*—To be a separate pavilion, something after the order of the pavilion at City Park. A large open pavilion capable of being closed for entertainments, if necessary, by means of a system of windows. At each end of the pavilion would suggest having a room, one for men, one for women. Also to have one toilet room for men and one for women.

14. Laundry, lighting, power, heating, and disinfecting plant all included under one roof. This building to be as far away from main buildings as compatible with efficient service. Laundry to be furnished with most approved machinery. The disinfection plant to be in a separate room, but to communicate with laundry.

15. *Power Plant and Stable.*—To be a suitable distance from buildings.

16. Every part of the sanatorium should be so constructed as to facilitate cleaning; all corners should be rounded, and unnecessary ledges avoided. All construction to be of the simplest durable nature. A well-lighted, dry cellar under all large buildings, with trunk rooms and storerooms. A brick conduit from power plant to main buildings for heating pipes, etc., large enough to admit the passage of a man throughout its course. The stairs in the different buildings to be built wide, having easy treads and rises. Each building to be provided with an electric call system in each room and on each floor. All buildings to be wired for telephone communication with administration building and medical building. Full fire protection on each floor for every building.

17. All windows and doors should be so constructed as not to clatter when the wind blows, or admit drafts from any possible shrinkage of woodwork after construction. Window sills to be rounded. Each room to have one door and one large window opening on to the veranda. The door should be wide enough to roll a bed through upon the veranda. Rooms should not be less than 12 by 14 feet; height of rooms on first floor not less than 10½ feet; height of rooms on second floor not less than 10 feet. All woodwork to be of hardwood, well filled and varnished or painted. Each room to have a closet, the floor of which should not be sunk below the floor of the room, and the interior to be made as carefully as that of the room itself. No transoms over the inside doors. No plumbing in rooms.

18. Verandas and covered balconies are an essential part of every sanatorium for consumptives, so arranged as not to darken the patients' rooms. To properly shelter the patients, the veranda should be 10 feet wide. The veranda floors should be so constructed as to properly shed water. Each sleeping-room to have a corresponding amount of veranda space, such space being separable by a properly adjusted canvas wall or curtain, stored in wall niche. The veranda front to have a solid wall with coping 2½ or 3 feet high. All doors and windows to be screened. All floors to be double floors of polished hardwood, either varnished, waxed or covered with a paraffin composition. Cracks and joints should be, as far as possible, avoided. Floors to be deadened. In bathrooms, washrooms, laboratory, kitchen, laundry, disinfecting room and corridors connecting buildings, cement, artificial stone, vitreous tiles, or "torgament" may be used, first having the space between beams filled with concrete.

19. All walls should be extra thick and deadened to prevent one patient from being disturbed by the coughing of another. Walls and ceilings must be of washable surface.

20. Artificial lighting should be by electricity, as other methods add to atmospheric impurity. All buildings should be wired for electricity and piped for gas in all rooms but the sleeping rooms.

21. Ventilation of rooms should be as perfect as possible. Each person should receive not less than 10,000 cubic feet of fresh air per hour while in a closed room. The impure air removed by shafts and heated central well.

22. The committee would recommend indirect heating, as this system seems to be the most efficacious in removing impure air and admitting fresh air. Hot-water heating is worthy consideration. All general gathering rooms to have open fire places.

23. The water-carriage system, with suitable cesspools. The water-pressure must be high enough to properly flush all pipes. If possible connect with city system. Provision must be made for living quarters for help. Sexes to be separated.

APPENDIX II.

Board of Trustees of the Agnes Memorial Sanatorium.—C. S. Morey, President; John Campion, W. S. Cheesman, T. S. Dines, C. J. Hughes, Jr., J. G. McMurtry, Treasurer; J. H. Sawyer, Secretary.

Medical Board of the Agnes Memorial Sanatorium.—Arnold Stedman, M.D., Chairman; W. H. Bergtold, M.D., Carroll E. Edson, M.D., J. A. Wilder, M.D., Secretary; L. B. Lockard, M.D.; G. W. Holden, M.D., Superintendent and Medical Director.

MEDICAL PROGRESS.

MEDICINE.

Determination of Different Forms of Albumin in Urine.—The ingenious method of determining the percentage of the different forms of albumin in nephritic urine, devised by A. Oswald (*Münch. med. Woch.*, August 23, 1904) depends upon the addition of various amounts of saturated solution of ammonium sulphate. Four Esbach albuminometers are selected and marked A, B, C, and D. In A, the entire amount of albumin is precipitated in the usual way with Esbach's reagent. The remaining tubes are then filled with urine up to the mark U; tube B then receives 2.8 c.c. of ammonium sulphate solution to 7.2 c.c. of urine, tube C 3.6 c.c. to 6.4 c.c. and tube D 5 c.c. to 5 c.c. Each tube is allowed to stand for twenty-four hours and the

precipitate then collected on a filter, dissolved in water poured into an Esbach tube and precipitated for quantitative determination with Esbach's reagent. The precipitate derived from tube B will equal the amount of fibrinogen or fibrinoglobulin, that from tube C minus B, the percentage of euglobulin, tube D minus C will equal the percentage of pseudoglobulin while the proportion of serum albumin is obtained by subtracting D from A. In a number of cases of nephritis examined serum albumin was always most abundant, then came pseudoglobulin and finally euglobulin, while fibrinogen was absent in all.

Complications of Polyarticular Rheumatism.—In the analysis of a large number of cases, P. Harrass (*Münch. med. Woch.*, August 30, 1904) finds that about 2.2 per cent. of all hospital cases are admitted for articular rheumatism. The greatest frequency is noticed between sixteen and twenty years and the sexes are affected about equally. In 26 per cent. an angina preceded the attack and recurrences were noticed in 39.7 per cent. Complications were observed in 57 per cent., but more frequently among women than men. The great majority of complications (51.7 per cent.) were cardiac and mitral insufficiency was the most frequent lesion observed. Pericarditis was observed in 1.7 per cent, less frequently erythema nodosum, pneumonia, chorea minor, psychical disturbances and nephritis. The mortality was 1.7 per cent., the cause of death being pneumonia and nephritis secondary to loss of compensation.

Paroxysmal Hemoglobinuria.—The hemolysis seen in paroxysmal hemoglobinuria is explained by V. Donath and K. Landsteiner (*Münch. med. Woch.*, September 6, 1904) as due to the absorption of a toxic body when the blood is cooled off. The solution of the cells then occurs when the blood is again warmed through the agency of a complement which is also present in normal serum. The process can be easily imitated by cooling and again warming the blood in a test-tube.

Alkaptonuria.—A masked case of alkaptonuria was detected by O. Schumm (*Münch. med. Woch.*, September 6, 1904) in a young man, twenty years old, whose antecedents and family history were absolutely negative. Though the patient's family was large, only one sister also excreted alkapton, without being in any way aware of the condition. The specific gravity of the urine varied between 1.021 and 1.030, polarized light was not affected and yeast did not cause fermentation. Indican, urobilin and uric acid were present in normal quantities. Immediately after passing, the urine was acid, and of normal yellow color, but it soon turned brown, even before ammoniacal fermentation set in. Upon the addition of lye, the upper portion became brown in a few seconds. Alkaline copper and ammoniacal silver solution were reduced with heat and on boiling with Nylander's solution, a brown precipitate was thrown down. Dilute chloride of iron added drop by drop, gives a transient blue color. Alkapton may be isolated by adding one-tenth the quantity of 20 per cent. sulphuric acid, evaporating to one-tenth the volume and extracting the residue with ether. On distilling the ether, a syrupy residue will remain, which soon crystallizes and from which homogentisic acid can easily be obtained pure. Even the excretion of as much as 80 grams of this acid daily did not interfere with the patient's well-being. According to modern views, alkapton is a decomposition product of albumin, which is still further burnt up in the normal individuals, but in certain rare cases, is excreted as such, without actually constituting a disease. Increased ingestion of albumin will thus increase the excretion of homogentisic acid. Rarely the condition is but temporary, as with some febrile disturbance.

OBSTETRICS AND GYNECOLOGY.

Results of Induced Labor.—Induction of premature labor in case of pelvic contraction has been condemned by many obstetricians because of the high fetal mortality. R. C. Norris (*Am. Jour. Obstet.*, September, 1904) is in accord with such teaching when the true conjugate is 7.5 cm. or less in a generally contracted pelvis or 7 cm. in the flat pelvis. When the conjugate is between 8 cm. and 10 cm., skillfully induced labor at the latest permissible period of pregnancy, has an important place. A delayed labor with the history of a previous difficult forceps delivery at term and even the avoidance of perineal lacerations likely to follow a breech extraction in a first labor with a normal pelvis, have been advanced as justifiable indications for Cæsarean section. The proper indication of labor finds its field of usefulness in almost all of these cases without resorting to Cæsarean section. To accomplish the best results after the induction of premature labor, the usual causes of failure, as far as possible, must be eliminated. These are the interruption of pregnancy earlier than the degree of contraction demands, or at too late a period, necessitating operative delivery of a premature child. An accurate determination of the degree of prematurity is important. The possibility of conception having occurred in the premenstrual and not in the usual postmenstrual days, may be a source of error of two to three weeks. When in doubt, if the relative size of the child's head will permit it, the induction of labor should be postponed a week or ten days from the date selected. Instrumental methods for determining the relative size of the head to the pelvis are inaccurate. Manual engagement of the head depends for accuracy upon individual skill and experience but is the most reliable. The average infant's biparietal diameter at term is 8.25 cm., a diameter that will usually pass a conjugate of 8 cm. The most satisfactory method of inducing labor consists in the proper introduction of a bougie, dilatation of a cervix, if necessary, and then the insertion of the largest size Voorhees bag upon the stem of which more or less continuous traction is made by means of a cord and weight. When the bag can be drawn through the cervix with gentle traction, instrumental delivery or version and extraction, if indicated, can be immediately performed when necessary.

Bathing During Menstruation.—It is the traditional belief of both profession and laity that it is advisable to omit bathing during the menstrual period. Customs among primitive people in regard to the bath during menstruation are much the same as those generally in vogue among the women of to-day. During the past ten years many physicians have either advised or sanctioned some form of bathing during this period. J. C. Edgar (*Am. Jour. Obst.*, September, 1904), believes, that women of ordinary strength and health are able to bathe during menstruation, following certain simple precautions, not only without any injury but with marked addition to personal comfort and benefit to general health. While there may be a certain amount of risk of infection of the uterus in tub bathing, the great harm obtained is by chilling

of the surface in improperly applied baths. All forms of bathing during the menstrual period are largely a matter of habit and usually can be acquired by cautious and gentle progression. Surf bathing, when the body surface remains chilled for some time, should always be excepted. A daily tepid sponge bath (85° to 92° F.) during the menstrual period is not only a harmless proceeding, but is demanded by the rules of hygiene. After the establishment of the menstrual flow, on the second or third day, a tepid tub or shower bath is a perfectly safe practice and can be acquired without risk in most women.

PHYSIOLOGY.

Absorption of Foreign Albumin from the Gastro-Intestinal Tract.—It is a strange fact, discovered by D. Ganghofer and V. Langer (*Münch. med. Woch.*, August 23, 1904), that foreign albumin introduced by mouth is partially absorbed as such by the gastro-intestinal tract of young animals up to the end of the first week of life. The same observation has been made upon the human infant for a somewhat longer period of time. The alimentary tract of older animals is impervious toward albumin of other species unless an excessive amount is ingested or the lining epithelum is the seat of an anatomical lesson or a mere functional disturbance. The absorption of unaltered albumin is followed by the production of antibodies which may be responsible for the general emaciation always noticed. The conclusions to be derived from these observations are that in very young infants and older children suffering from gastro-intestinal disturbance, only human albumin will be tolerated.

GENITO-URINARY AND SKIN DISEASES.

Etiology of Eczema.—Despite all that has been written and said about eczema, the etiology of this most-common skin disease is still obscure. E. v. Düiring (*Münch. med. Woch.*, Sept. 6, 1904) cannot share the view of Unna, that eczema is primarily a parasitic disease for the vesicles of the early stages have time and time again been proven sterile and even inveterate cases will sometimes heal with treatment which is directly opposed to all rules of asepsis. Most likely a specific predisposition combined with a local or general irritation are the underlying causes and more good can generally be accomplished by attention to diet and mode of life than by antiseptic local dressings. There is a distinct relationship between skin and the internal organs, thus an eczema of the head, when treated energetically will sometimes be followed by compensatory hyperemia of the brain, manifesting itself in convulsions, and an intercurrent attack of diarrhea, will frequently improve an eczema of the body.

THERAPEUTICS.

Treatment of Insipid Diabetes.—In a typical severe case of diabetes insipidus, B. Stein (*Münch. med. Woch.*, September 6, 1904) has tried a number of different therapeutic measures with the following results: Change in diet did not decrease the amount of urine while it made the patient very uncomfortable. Decreasing the amount of fluid ingested was also a failure since severe nausea, vertigo and weak pulse were the result and the amount of urine dropped only from ten to eight liters. Cold baths were refreshing but warm water, applied in the hopes of stimulating diaphoresis, was not borne well. Preparations of valerian, large doses of antipyrin, the bromides, arsenic, sodium kakodylate, mercury, and the iodides did not make a lasting impression upon the disease, but good results were finally seen from small, gradually increasing doses of strychnine, injected subcutaneously. Polyuria and polydipsia disappeared in three weeks and the patient rapidly gained in weight.

PATHOLOGY AND BACTERIOLOGY.

Action of Fluorescent Substances on Normal and Hemolytic Sera.—If rabbit serum which dissolves the erythrocytes of some other blood, be mixed with a small amount of eosin solution and exposed to sunlight, it will completely lose its hemolytic properties in a short time while control mixture not exposed to the light, or serum exposed to light but not containing any eosin, will behave normally. If normal rabbit serum is added to the tubes which contain eosin and which have been exposed to light, hemolysis will eventually take place, showing that the expanse has destroyed the complement of the serum without affecting the amboceptors. The complements are therefore influenced in the same way as the toxins of diphtheria and tetanus bacilli. It is probable that the complements will also be destroyed in the circulating blood under the influence of eosin and sunlight.

Oxidizing Action of Fluorescent Substances.—According to D. Edlefsen (*Münch. med. Woch.*, September 6, 1904) the peculiar germicidal action of fluorescing substance is solely due to oxidation. The chemical best suited to prove this is beta-naphthol, since it is easily oxidized and its oxidation product can be readily detected. If quinine or eosin is mixed with beta-naphthol solution and then exposed to sunlight, the naphthol will be oxidized into beta-naphthochinon. This will give a bluish-green color if a few drops of resorcin solution and ammonia are added, changing into cherry red with nitric acid. A similar mixture kept in the dark even for days does not give this reaction. One of the strongest fluorescing substances and hence, oxidizing agents in sunlight, is azoresorufin.

SURGERY.

Prevention of Post-Operative Intestinal Paresis.—The behavior of the bowels the first few days after laparotomy is always a source of concern to the surgeon. D. H. Craig (*Am. Jour. Obstet.*, September, 1904) advocates the use of eserine salicylate hypodermatically in all cases of intra-abdominal operation Belonging to the groups of spinal depressants, eserine lessens or inhibits the inhibiting impulses ordinarily sent to the intestinal musculature through the splanchnics as a reflex result of peripheral irritation. If given in full dose (one-thirtieth gr.) at the time or immediately after opening the abdomen, the muscular and nervous mechanism of the intestine will be left in practically the same condition as before operation, in this way intestinal paresis is prevented. In many cases the bowels move in from twelve to forty-eight hours after operation, an absence of any movement during this period indicates thoroughness of preparation. A patient should be carefully watched for signs of intestinal paresis after the administration of eserine for the drug may fail because of poor preparation, too old a preparation, or because of idiosyncrasy on the part of the patient. Eserine cannot be expected to wholly overcome the paresis due to sepsis. When the drug fails, the possibility of mechanical obstruction should be borne in mind.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, OCTOBER 29, 1904.

PRACTICAL DIPHTHERIA SERUM THERAPY.

There are very few physicians now and fortunately the number is growing ever fewer who are not fully convinced of the efficacy of diphtheria antitoxin for the treatment of what used to be considered the most fatal of children's diseases.

Notwithstanding the almost universal agreement as regards the use of serum there are still marked divergences of opinion as to the amount to be given, the repetition of the dose, the necessity for other treatment and the care of convalescence. Not a little light was thrown on all these questions at the recent meeting of the New York State Medical Association, as can be seen from the proceedings printed in this week's Medical News (see page 858). There have been other contributions to the subject, a review of which in connection with the discussion of last week may prove of special interest at this time when we are entering on the period of greatest seasonal frequency of the disease.

All are agreed now that the initial dose of the diphtheria antitoxin must be much larger than was suggested a few years ago. One thousand five hundred antitoxic units was considered a greater dose than was needed in the average case five years ago. The American Pediatric Society's committee limited the first dose except in large children and severe cases to 2,000 units. Now every one commends 3,000 units as the least that should be given and 5,000 units if the case presents any serious feature. Even from this point the standard has an upward rather than a downward tendency. 10,000 units are suggested as not too large in severe laryngeal cases, or at least 5,000 units repeated in a few hours.

The question of dosage does not depend so much on the age of the child as on the severity of the symptoms. Even for an infant, if there are threatening symptoms of extensive nasal or laryngeal involvement, 5,000 antitoxic units should be given at once, to be repeated at the end of twelve hours if there is not a prompt abatement of the symptoms. Repetitions of the original dose depend entirely on the effect that is secured. If there is a drop in temperature, relief of breathing, a quieter pulse and generally a more comfortable condition, especially if the membrane assumes a granular appearance and begins to disintegrate or clear up, the dose need not be repeated. If these favorable changes are not noted, however, then delay beyond twelve hours in renewing the attempt to neutralize the diphtheria toxins present in the circulation is of serious significance and means the assumption of an undue responsibility on the part of the physician. If in doubt when there has been but a partial reaction and only a slight remission of symptoms, it is better to be sure than sorry and repeat the dose.

For the repetition of injections the same rule holds as with regard to the administration of the initial dose. Whenever there is a well grounded suspicion of the presence of diphtheria, especially if it occur in a child not over strong or if the symptoms are at all threatening, antitoxin should be administered at once without waiting for the bacteriological diagnosis. Even if the affection proves to be non-diphtheritic, no possible harm can be done and the contingency of subsequent urticaria cannot be permitted to weigh in the balance against the immense advantage of the early administration of antitoxin in genuine diphtheria. Even in severe streptococcic infections the diphtheria serum will not hamper the natural power of resistance, and while there is no doubt that streptococci may cause serious damage to the kidney, there is practically universal agreement that the serum will not add to the danger of nephritis.

As regards other treatment in addition to antitoxin injections there is some difference of opinion with the weight of authority in favor of not using local treatment especially if it tends to lessen the dependence on antitoxin as the main stay in the disease or if by mechanically modifying the appearance of the membrane it masks the progress of the case. As regards general supporting treatment there is no hesitation or disagreement. The resistive vitality must be kept up by means of strychnine or iron and the appetite must be encouraged in every way. Patients should be tempted at two hour intervals when not asleep, to take milk and other easily digestible foods. Plenty of liquid must be given, and this is frequently omitted because of difficulty in swallowing. Neglect of this, however, leaves the system with accumulating toxins when they might be washed out through the kidneys. For similar reasons the emunctories generally should be stimulated.

At the time of the convalescence, however, the use of local applications or sprays of hydrogen dioxide becomes almost imperative. Antitoxin neutralizes directly the toxins of diphtheria but it is not even in the slightest degree bactericidal. It has no effect upon Klebs-Löffler bacilli in the tissues or on the mucous membrane. These are usually thrown off during the reaction that follows the release from the burden of toxemia that has been clogging all normal action. Sometimes, however, the organism crippled by diphtheria is not able to do this promptly and there may be a renewal of the symptoms, or diphtheria bacilli may continue to live in the throat and be a source of danger to others for many weeks. It is in such cases especially where, because of laboratory diphtheria though there are no clinical symptoms and with regard to which boards of health very rightly refuse to raise the quarantine, the use of antiseptic sprays are especially valuable.

In general it may be said that under such proper care as has been here outlined, if applied promptly, diphtheria ceases to be the dread affliction that it used to be.

DR. OSLER ON IMMORTALITY.

There is a pleasure in store for all observers and thinkers in scientific ways, who have also emotions to be considered, in Dr. Osler's address on Science and Immortality, which was delivered at Harvard University, as one of the Ingersoll lectures, and which has since been published in the form of a small book.

It is interesting to know that physicians had been asked in vain to express themselves upon their belief in immortality, before this Harvard audience; interesting because the feeling is implied that the physician must speak the truth as he finds it, not as it behooves him to shape it to a creed, interesting that Dr. Osler himself and others of his colleagues did decline, feeling that Immortality was as far too great a subject for them to speak upon as was Life itself. That he finally consented was doubtless with the feeling that it might help others whose emotions and whose consciences were in conflict to realize that one might face the question frankly, in company with Plato, Job and Sir Thomas Browne, without any reference to the formal expressions of their own individual creeds.

The skill of Dr. Osler's treatment of this untreatable subject lies not in discussing whether science proves that there is or is not a life to come, but in showing how little science has to do with a question that lies wholly beyond its ken. The charm of the lecture lies in the frank, simple way with which he states fundamental truths that exist as such, despite the church's desire to build upon them hopes and beliefs in immortality; and despite the scoffers desire to break them into stones to hurl at believers.

The passionate longing of the human heart for "the touch of a vanished hand, and the sound of a voice that is still" is recognized, as well as the burning mystery of existence that at times forges a man into a mere link in an endless chain moving mechanically in its monotonous round, and again lights his torch on the mountain top, while he peers amid the shadows to see what lies beyond. That there may be something beyond this life the poets and the sages admit, nay, hope for, but Dr. Osler states very straightforwardly that "of the things that are unseen science knows nothing, and has at present no means of knowing anything." What weight may be given to arguments, hopes, longings based upon emotions of the heart he does not try to say. But he does say that "To keep his mind sweet the modern scientific man should be saturated with the Bible and Plato, with Homer, Shakespeare and Milton. To see life through their eyes may enable him to strike a balance between the rational and emotional, which is the most serious difficulty of the intellectual life."

"WITH THE HELP OF A TOOTH-BRUSH."

England is nothing if she is not conservative, and her colonies, as a rule, surpass her in out-Heroding Herod in her insular dogmas. This is as true in regard to her medical absorption and inhibition as it is in all else, with the exception perhaps, of her powers of expansion in regard to the acquisition of new territory, but for once she has succeeded in being more thoroughly British than even Canada itself.

It seems that the municipal authorities of Folkstone, Kent, England, have the support and management of an institution for indigent children of both sexes under their jurisdiction, and that the Mayor of the town is directly responsible not only for the distribution of the funds used, but is also the arbiter in the Council as to what is necessary for the welfare of its inmates. At a recent meeting of the Board, after action had been taken on the necessary expenditure of the pounds, shillings and pence of the appropriation for the construction of a new dormitory for the children and the proper equipment and furnishing thereof, a timid member, who must have had a drop of alien blood in his composition, haltingly suggested that a small unexpended balance should be devoted to the formation of a fund for the purchase of tooth-brushes, and moved that their daily use should be made obligatory on all the beneficiaries of the institution.

Then the Mayor of Folkstone arose in his wrath and delivered a speech that for patriotic warmth and fervor of expression and thorough and hearty appreciation of the blessing of having remained an Englishman, will live long in the memories of his auditors as a direct refutation to the belief that public speaking is one of the lost arts in the British Isles. What peculiar grudge this worthy man bore against the harmless and inoffensive tooth-brush it is hard to say; judging from his impassioned words it could hardly have been a personal one, as in all probability he had never rubbed against one or been brought in contact with it in any way. Rather it seems, he regarded it as only one of the factors that as he says "have led to the degeneracy of the nation, and which have increased the effeminacy of the race, robbing it of its virile force and rendering it weak and puerile." Britons, he gravely assured us, as many others already have, "never can be slaves," but the step he declares is a short one, that "will lead the United Kingdom to the fate that befell imperial Rome in the zenith of her effulgent power, if her offspring yield to the soft blandishments of the tooth-brush and persist in the enervating habit of forcibly removing the soil of Old England that "clings deeply and darkly" to the finger nails of her future bulwarks. Better the senility of poor old Uncle Ned, with the consequent necessity of letting the hoe-cake be, than the death of all moral perception and the premature decay of racial rectitude. Evidently to this moral magistrate the ounce of "stopping" is not worth the £ of cure, and early manhood sans teeth does not outweigh, in his thoroughly insular scales, the prospect of advanced old age, sans everything.

Luckily for us, who are not only the direct descendants of this stolid stock, but are proud of it, the lump seems to have been leavened by the yeast of the struggle for existence in the early colonial days. This in continuous years by the weeding out of the survival of the fittest, has increased until the pendulum has swung a little to the other side and the massive and ponderous British John Bull has, by the process of evolution, blossomed out into the alert and quick-witted American "Johnnie on the Spot." This is apparent not only in the professions, but also in all business operations, and there is not a trade or trades-union in the country that is not quick to take advantage of any possible opportunity to advertise their wares, particularly when they can add it as a rider to a bill that is connected with public hygiene or sanitary improvement.

Thus, the action of the convention of the United Master Bakers' Union, recently held in St. Louis, in doing away with the labels which have hitherto been pasted on the loaves of bread, was a master stroke from the standpoint of diplomacy. For while we have been taught that man shall not live on bread alone, yet it does, in one form or another, enter so largely into the diet of us all that it has fairly earned its sobriquet "of the staff of life," and is about as much of a necessity to the masses as the air that they breathe or the water which they drink. Bread, moreover, unlike whiskey, varies very little in quality, and while some loaves may be a trifle larger than other loaves, there is, as a rule, no such thing as bad bread on the market. For there is a certain standard that all bakers must live up to in these strenuous days of competition in order to exist as the time has passed when the union laborer will ask for bread and accept

a stone in return. To him the entity of the manufacturing baker is nothing, for unlike the Englishman with his hat, he does not care to "see his maker's name," and provided only that the bread is fresh and the loaf is of full size, he is content. He is not buying trade labels of red, white and blue, and as he does not intend to cast his bread upon the waters, with an ultimate prospect of again finding it, he is utterly indifferent to any scheme of chromatic embellishment or pictorial ornamentation.

Judging from a sanitary view point, the whole matter is largely one of sentiment. The labels are affixed while the dough is still fresh, and as the adhesive matter is a flour paste, there is little difference between the two when the process of baking is complete. There has been, to be sure, some handling in both cases, but fire is by no means an inert purifier and there is little or no danger of infection from their use, even if the labels were eaten with the bread, which is not the case. In fact, the risk is not to be compared with that of the deadly shine on the prize apple at the corner fruit stand, or to that refused by the refractory child who emphatically declared that "company or no company, she would not have her face washed with spit." So that taking one consideration with another Patter-cake, Patter-cake baker man seems to have scored a point. For it will be a simple matter to have the names stamped out in the bread pans, while they have achieved a reputation in the community for purity of purpose that is synonymous with that of their own baking powder, and second only to that of the "pure young man" in the opera of "Patience."

The only wonder is that they have succeeded in getting there *first*, before some provincial board of health had made the mosquito-cleared welkin ring with the echoes of this "label-ous" iniquity. But reform, unlike charity, does not begin at home, and the story of the mote and the beam is not only biblical, but proverbial.

ECHOES AND NEWS.

NEW YORK.

Big Class for Bellevue.—Seventeen candidates for entrance to the University and Bellevue Hospital Medical School have been turned away for want of accommodation. The total enrolment of this institution is now three hundred and sixty.

Gift to Nassau Hospital.—Mr. George Arents, father of George Arents, Jr., who was injured by the overturning of his machine during the Vanderbilt Cup race on October 8, has presented $1,000 to the Nassau Hospital, where the younger Arents was taken after the mishap.

Award to Dr. Knopf.—The Superior Jury of Awards of the St. Louis Purchase Exposition has just awarded Dr. S. A. Knopf, of this city, a gold medal for his works on the prevention and treatment of tuberculosis, which were exhibited in the Section of Hygiene and Social Science.

Dr. Lambert Dean at P. and S.—The Deanship of the College of Physicians and Surgeons of Columbia University, held by Dr. John G. Curtis as Acting Dean since the resignation of Dr. McLane in June, 1903, has been filled by the election, for the statutory term, of Dr. Samuel W. Lambert, Professor of Applied Therapeutics. Dr. Lambert is the son of the late Dr. Edward W. Lambert, and graduated from Yale with the degree of A.B. in 1880, and with that of Ph.B. in 1882. He graduated from the College of Physicians and Surgeons of Columbia University in 1885. Since 1896 he has been one of the visiting physicians at the New York Hospital. Dr. Lambert becomes ex officio a member of the Columbia University Council, of the Board of Trustees of the Roosevelt Hospital, and of the Boards of Managers of the Sloane Maternity Hospital and of the Vanderbilt Clinic.

New York Eye and Ear Infirmary.—The Directors of the New York Eye and Ear Infirmary, at their recent annual meeting, listened with the greatest satisfaction to the report of the Treasurer, John L. Riker, showing that the institution had been saved from practical suspension through the generous donations of charitable persons. At the beginning of the fiscal year the infirmary found itself with a deficit of $22,000. It was determined to keep the running expenses of the infirmary within its income, preserving intact the endowment acquired by gifts and legacies as perpetual funds. This necessitated the closing of the Platt Pavilion for Contagious Diseases on March 1, and later the number of cataract ward beds was reduced from fourteen to ten. This meant that within the year sixty-eight persons suffering from a disability that could have been removed were turned away. When the institution found itself with a big deficit circular letters were sent and personal appeals made to friends for contributions, with the result that the debt was wiped away and a balance acquired. A careful estimate of all available sources of revenue shows that, with the amount of charitable work which the infirmary is called upon to perform, even with the present limitations, more than the balance now at hand will be required for the coming year. The money which the institution annually needs above current receipts varies from $10,000 to $20,000. The demands of the work grew yearly, calling for increased accommodations, which have been provided for by gifts for building purposes, but the endowment for carrying on the expenses of the enlarged plant has not grown proportionally. The nose and throat department was given up for this reason two years ago. If the financial condition of the infirmary will warrant it this will be reopened.

The officers chosen for this year are: President, James J. Higginson; First Vice-President, J. Harsen Rhoades; Second Vice-President, W. Emlen Roosevelt; Treasurer, John L. Riker; Secretary, Dr. W. E. Lambert. Among the plans for raising funds for the infirmary is one for an exhibition of the best works of 100 American artists and 100 European artists at the American Fine Arts Galleries, beginning in the middle of November and lasting until the middle of December.

Pneumonia Inquiry Begins.—A systematic attempt to solve one of the most important sanitary problems

in the world was begun last week, when the Pneumonia Commission met in the offices of the Board of Health to consider means of preventing the spread of pulmonary diseases. The commission is composed of Drs. Edward G. Janeway, Emmett Holt, Hermann Biggs and Health Commissioner Darlington of this city; Drs. William Osler and W. H. Welch, of Baltimore; Dr. Theobald Smith, of Harvard, and Drs. John H. Musser, of Philadelphia; T. Mitchell Prudden, of the College of Physicians and Surgeons, and Frank Billings, of Chicago. At the request of Dr. Darlington the city appropriated $10,000 several months ago for the investigation, and it is expected that the deliberations of the commission will extend for at least a year. The object of this commission was thus set forth by Dr. Darlington in his address to the meeting: "For some years the problem presented by the large and constantly increasing death rate from the acute respiratory diseases has been the cause of serious anxiety to the Board of Health. This problem has long been recognized as one of the first sanitary importance, and efforts have frequently been made to find some method for its solution. Succinctly stated, the situation is this: During the last twenty years the general death rate in New York City has fallen 25 per cent. and the death rate from all the principal causes of deaths have fallen from 10 to 40 per cent., excepting in four groups of diseases, in which there has been an increase. These are: (1) the acute respiratory diseases, (2) cancer, (3) the diseases of the heart. (4) disease of the kidneys. The increases in these groups have been from 10 to 25 or 40 per cent.; in the acute respiratory diseases being about 15 per cent. In the present year there has been an extraordinary increase in the first half, the deaths from the acute respiratory diseases forming no less than 23 per cent. of the total death rate, or 18,000, of which 8,630 were from pneumonia. There can now be no question that the exciting cause in each one of the diseases of this group is a micro-organism, which requires such conditions for its growth and multiplication as are found in the living body. These organisms, practically, do not multiply at all outside of the tissues or cavities of the body under natural conditions. The infection, therefore, must practically always be the result of communication, directly or indirectly, from one human being to another. The conclusion, then, seems justifiable that these diseases are essentially communicable, and however great the inherent difficulties of the problem may be, theoretically at least, they should be to a greater or less extent preventable." The subjects discussed by the commission yesterday afternoon and evening were frequency and variation of occurrence, evidence of communicability, mouth infection, seasonal relations, collection of statistics and geographical relations. Dr. Janeway was chosen chairman of the commission, which was subdivided into a clinical committee and a bacteriological committee. The former is composed of Drs. Janeway, Osler, Musser, Billings and Holt, the latter of Drs. Welch, Prudden and Smith. Dr. Biggs will serve on both committees.

PHILADELPHIA.

Warning Against "Walk in" Signs.—A physician of this city was recently robbed of an oil painting valued at $100 by a woman who came in shortly before the close of his office hours. He now warns the profession against the use of the "Walk in without ringing" sign, which is used by so many physicians during office hours. It is apt to invite thieves as well as prospective patients.

Nurses Will Soon Return.—Dr. Anita Newcomb McGee and the corps of nine nurses who have been in Japan during the past six months, are soon to return after rendering valuable service in the various army posts of Manchuria. They were to leave Nagasaki on October 23. The Associate Society of the Red Cross of Philadelphia, under whose auspices they were sent, is planning receptions for them in San Francisco and Philadelphia.

Miners' Hospital Enlarged.—The new building of the State Hospital for Injured Persons of the Anthracite Coal Region was formally opened at Ashland, October 19. The new structure is a wing of the main building, and is one of the finest in finish and equipment of the hospitals in the State. Dr. L. Webster Fox, of Philadelphia, was the guest of honor at the dedication.

Married by 'Phone in Smallpox Ward.—The first marriage by telephone in the city of Philadelphia was performed on October 18 by Magistrate Macleary. The persons to be married were in the smallpox ward of the Municipal Hospital, where the man had been taken some days before. He was seriously ill with the disease, and his fiancee insisted upon the ceremony being performed. Enlisting the aid of influential persons she obtained permission, and the details were arranged. The magistrate asked his questions on the 'phone and the answers of the parties in the hospital were witnessed by the superintendent, physicians and nurses. The man died seven hours after the ceremony.

Births of Males Increase.—Exact figures are not at present available, but it is known there has been an increase in male births in the city during the past months. A force of clerks is now at work on the vital statistics, and the exact gain will be known in the near future. The increase is stated to be ten per cent. during the past ten months.

Officers of Pathological Society.—The Pathological Society of Philadelphia, at the annual election held on October 13, elected the following officers: President, Dr. Alfred Stengel; Vice-President, Drs. Joseph McFarland, W. M. L. Coplin, Allen J. Smith and M. P. Ravenel; Secretary, Dr. D. J. McCarthy; Treasurer, Dr. T. S. Westcott; Recorder, Dr. D. L. Edsall. The President, Secretary, Treasurer and the majority of the Vice-Presidents were re-elections.

Copper Versus Typhoid.—Dr. George T. Moore, chief of the laboratory of Plant Physiology in the United States Department of Agriculture, addressed the Philosophical Society of Philadelphia October 21, on the subject of copper as a bactericidal agent in the purification of water. He elaborated points previously mentioned in our notes as to the efficacy of copper sulphate and colloidal copper in destroying algae and typhoid and cholera bacilli. Efficiency, harmlessness and economy are the three considerations in the purification of water, and copper meets all these requirements. Letters stating the efficiency of the process were read and authorities quoted as to the non-poisonous qualities of the solution employed. As to the cost, it was stated that reservoirs holding 80,000,000 gallons had been treated for algae at a cost of $50. Some of the members of the Philadelphia health department are of the opinion that the city should, in view of the successful laboratory experiments recently carried out, allow the use of one of the reservoirs to test the process on a large scale.

Notable Victory for Pure Food.—Charles W. Spencer, one of the firm trading as the Kansas City Beef Company, has been convicted of selling meat on which a preservative was used. The trial was a notable one,

as being a test case regarding the use of sodium sulphite, and also because of the eminent witnesses engaged. A preservative company, said to be in New York, which supplied Spencer the material employed under guarantee of harmlessness, was backing the defendant in the suit. The preservative, known as Three X preservaline, was acknowledged to contain 88 per cent. sodium sulphite, 10 per cent. of boracic acid, and 2 per cent. of sodium bicarbonate. The chief witness for the defendant was Dr. Oscar Liebreich, of the University of Berlin, who was brought from St. Louis for the purpose. Dr. Liebreich admitted that he was at odds with the German Government regarding the harmlessness of certain food preservatives, but asserted his belief that some of their laws will soon be repealed. When asked if he considered good for Americans what his government had forbidden for Germans, he said German laws were political as well as health laws. It is reported he was paid $4,000 for his testimony. The jury returned a verdict for the Commonwealth.

CHICAGO.

Must be Examined Before Appointed.—Chicago surgeons and physicians who have practiced for thirty years, and whose names are known to medical men from New York to California, hereafter will have to pass the same examination as the most callow graduate of the smallest medical school in the country before they can be placed on the staff of attending physicians at the Cook County Hospital, according to the measure adopted October 21 by the County Board. Under the terms of a resolution presented by President Foreman, the Board voted to place all attending physicians and surgeons under civil service rules, as well as to reduce the staff to 65. The staff at present numbers 113.

Political Pull Doomed.—Political pull is doomed at the hospital as a result of the Board's action, which is declared to be one of the most important taken for years in relation to introduction of civil service at a county institution, and one of the reasons for the new arrangement is the enormous pressure being constantly brought to bear on the County Commissioners by those who want appointments. The lessening of the size of the staff and the making of the positions permanent will work great good to the hospital, it is thought by Mr. Foreman. Responsibilities will be better divided, and it will generally be found of the first importance to the welfare of the patient.

Ghoul Plot in Hospitals.—It is said that certain hospital authorities of this city were recently charged with catering to favorite undertakers in the matter of disposing of the bodies of persons who die in the institutions. The impression was given that the hospitals are receiving a commission from undertakers. While no direct charge was made, the insinuations were unmistakable. These accusations were made by Dr. Behm, vital statistician of the Health Department, and by a delegation of undertakers headed by former Alderman Sloan, to the Council Health Committee. So thoroughly convinced were the Aldermen of the truth of the accusations that an ordinance intended to stop the unjust practice was recommended to the Council for adoption.

Arrest of N. News Wood.—Reviving the sensational charges made by Dr. John B. Murphy against the Christian Hospital in his injunction suit last year, Dr. N. News Wood, President of the Hospital, was attached October 19 for contempt of court, and was given until October 25 to show cause why he should not be punished. Dr. Wood was arrested on complaint of Dr. Murphy, and was at once taken before Judge Holdom. He was finally released on $1,000 bonds, signed by his wife. The injunction which Dr. Wood is accused of violating restrained him from using the name, signature or picture of Dr. Murphy in any way in connection with the hospital, or from representing in any way that Dr. Murphy has or ever has had any connection whatever with the establishment. In his bill Dr. Murphy charged he had never heard of the Christian Hospital, and denounced the use of his name as fraudulent. It is now charged that Dr. Wood has been selling membership certificates with the picture of Dr. Murphy upon them, and is still using Dr. Murphy's name in his business, notwithstanding the order of the court.

State Asked to take Insane.—A movement has been started by the County Board to seek legislation transferring the Dunning Hospital for the Insane from County to State management. The plan, which originated with President Foreman, provides for a division of the institution. It is proposed to transform Dunning entirely into a State Insane Asylum, and establish the Home for the Poor and the Hospital for Consumptives on some large tract of land farther from the city. The Board unanimously approved the proposition and referred it to the Committee on State Legislation. They will petition the State Board of Public Charities to recommend to the General Assembly at the approaching session the enactment of the necessary legislation for the transfer.

Division of Fees.—The following decoy letter, signed by "J. C. Evans, M.D., Odell, Illinois," was sent to one hundred Chicago surgeons and physicians, asking whether or not they would pay the writer a commission for referring a patient to them:

"My Dear Doctor.—I have a case under my charge which requires attention along your line of work. I am not quite sure of my diagnosis, but will leave that whole matter to you. The people have heard of you favorably, and are inclined to go to you for treatment. As they are wealthy they ought to pay a good fee for the service. Now, doctor, you understand that I am a young man just starting a practice, and in small towns we cannot make any distinction between the rich and poor in the matter of charges. I have only received my regular visiting fee in this case. I understand, however, that it is customary for physicians to pay a commission of 25 per cent. upon all referred work, and I will deem it a favor if you can take care of me in this matter. Kindly let me hear from you by return mail, as I am anxious to bring the case to you at once if satisfactory arrangements can be made. Yours truly."

The result of these letters was 18 acceptances, 26 declinations, and 56 failed to answer. The decoy letter was published in the *Chicago Daily Tribune*, October 17, with the substance of the letters of the gentlemen who made acceptances, publishing their names. It is believed that one or two local physicians instigated this matter, and then turned it over to the *Chicago Daily Tribune*. The profession in general is very much incensed at this underhand method of exposure, and no doubt the matter will be thoroughly aired at a subsequent meeting of the Chicago Medical Society or its Council.

Death for Insane and Incurable.—At the National Prison Congress, held at Quincy, Illinois, October 19, according to the press dispatches, Dr. Henry G. Hatch, of Quincy, advocated homicide or the right to let a person take his own life when he is found to be incurable; and also he would have the State dispose of the permanently insane and incurable by putting such persons to an easy death. He also favored sterilization to prevent the increase of the criminal class. He would

have the State prevent the marriage of undesirable persons, and would forbid the saloonkeeper selling liquor to the habitual drunkard. Several physicians have been interviewed regarding the view promulgated by Dr. Hatch, and have denounced it in vigorous terms.

Is Consumption Hereditary?—Dr. Charles L. Mix, in a popular lecture on this subject, denied Dr. Koch's theory of hereditary predisposition to tuberculosis. He cited statistics to show that the disease is merely a result of infection or exposure. Members of families in which consumption has appeared need not be haunted by a fear of the disease, provided they do not expose themselves to the tubercle bacillus; nor should members of families in which it has not appeared believe they are immune. The hereditary thory is based on the unscientific argument that since consumption appears in certain families and not in others it must be inherited. No satisfactory theory why consumption is more frequent between the ages of 20 and 30 has ever been advanced. Why do one-third of all stenographers die of consumption and only one-tenth of those engaged in outside work show hereditary predisposition? Why do bookkeepers show a death rate of nearly 28 per cent.? The reason that girls suffer more from consumption than boys is because they are at home taking care of the consumptive parents.

Deformities of the Nasal Septum.—Dr. Chas. M. Robertson read a paper on this subject before a recent meeting of the Chicago Laryngological and Climatological Society, in which he enunciated the following points: (1) The sawing off of a ledge or spur will often give more room than would appear possible at the pre-operative examination. (2) Great care in saving mucous membrane in these cases is not so important as is usually believed, as it is usually hypertrophied and, therefore, a diseased tissue. (3) The precaution of avoiding a perforation which he had seen less than a dozen times in his operative life. (4) The impracticability of "V"-shaped operations as made by files and knives on small deviations, the consequent packing into place till the septum has regained its rigidity. (5) The utter failure of all crushing operations as they are brutal and unsurgical, aside from being impractical, from the fact that it is impossible to make the circumference of an arc fit into a space the length of a segment of same. (6) The ease and success of the Gleason method in most cases where there is no external deformity. The advantages in the short time that packing is necessary. (7) The absence of firm cartilaginous support in the window resection operation, and the liability of one or more perforations occurring during operation or healing. (8) The importance of saving all tissue possible that has function and is not diseased. (9) The total disregard of so many surgeons to this class of nasal stenosis, and the great benefits accruing from such operations on special functions and the general health of the individual.

Invisible Droplets of Sputum Expelled in Talking.—Dr. Alice Hamilton read an interesting paper on this subject before the Chicago Medical Society, in which she embodied the results of experiments that were carried on in the Memorial Hospital of Infctious Diseases. Recent bacteriological investigations show the streptococcus invariably present in cases of scarlet fever, yet in many cases it is of low virulence. Scarlet fever may run its course without any streptococcus complications when streptococci are present in the tonsils. A member of the hospital staff contracted a severe rhinitis and pharyngitis when in attendance upon a case of scarlet fever. Another contracted streptococcal tonsillitis after his first visit to the ward, and organisms were found not only in the throat, but in the blood A third contracted streptococcal tonsillitis after having performed an autopsy on a case of scarlatinal sepsis. It is well known that nurses suffer from sore throat soon after going on duty. Last spring, to prove whether the streptococcus was actually disseminated in the air by scarlet fever patients, plates were held before the mouths of children, who coughed or cried, from half a minute to one minute, the expirations being forcible, and of fifty patients examined, the results were not uniform so far as the number of colonies was concerned. A good deal depends upon the dryness of the mouth, etc. The colonies on plates varied from one to 75, and the proportion of streptococci varied also. Of fifty patients, 47 were found by cultures made from swabs to have streptococci upon the tonsils; 33 expelled streptococi in coughing, crying, or breathing forcibly with the mouth open. In some the number of streptococcus colonies was less than one per cent.; in others it rose to over 50 per cent., there being an average of 20 per cent. Of 34 children who coughed or cried, 20 of them had streptococcus colonies. Of 16, who simply breathed heavily, 13 expelled streptococci. These cases represented all varieties of scarlet fever, and the observations and cultures were made during the first three weeks of the disease. After detailing further experiments and observations, Dr. Hamilton said, among other things, that surgeons and nurses may be the source of septic infection of patients even after the ordinary precautions have been taken. Surgical dressings prepared beforehand and indeed at the time of operation by nurses whose mouths were unprotected, and who must necessarily speak to each other occasionally, may be fraught with danger. There was undoubtedly more or less danger from the germ-laden sputum of the average surgeon who keeps his face close to the wound when describing the technic of an operation to the class.

The Management of Bright's Disease.—Dr. Alfred C. Croftan, in a paper with this title, read before the same Society, stated that the terms Bright's disease, nephritis and albuminuria are not infrequently used synonymously. It seems almost trite to correct this popular misconception by the statement that Bright's disease may be and often is the cause of nephritis; that nephritis may be due to Bright's disease, but may also be due to a great number of other causes. Finally, albuminuria is a common, though not a determining symptom of almost any form of nephritis. The expression "Bright's disease of the kidney" is, therefore, not so wrong as many are inclined to think, although the expression "the kidney of Bright's disease" would be more correct. The most modern views in regard to Bright's disease seem to be that his clinical entity is primarily a cardiovascular disorder of manifold origin The old postulate, and the one most commonly accepted even nowadays, was that the kidneys for some reason of other became primarily involved, and that as the result of this renal inadequacy certain excrementitious urinary bodies were retained in the blood and tissue juices, and there produced all the symptoms of Bright's disease, including the cardiovascular changes. Since we have learned to understand that in many instances the cardiovascular changes precede the nephritic changes; that many cases of Bright's disease progress to a fatal termination, with practically no involvement of the kidneys, or only very slight degrees of renal inadequacy, we have been forced to abandon this conception, at least for the overwhelming majority of cases. After considering the theoretical possibility that some poison or group of poisons may affect simultaneously the

heart, arteries and kidneys, the author stated that the other most important signs of Bright's disease are to be attributed to serious impairment of the kidneys, and are the inevitable result of any nephritis. He referred in particular to the edemas, to the retention of chlorides, and other well known signs of renal inadequacy. What the causes of this general intoxication, affecting chiefly the cardiovascular apparatus, may be, remains undetermined. He thinks there is very little doubt that in many instances chronic gastro-intestinal disorders can be incriminated, and that abnormal putrefactive processes in the bowel, or abnormal disassimilation of the food products, as a result of perversion of the gastro-intestinal function, can be made responsible. All prophylactic and causal treatment must be directed towards the correction of any gastro-intestinal perversion, or any hepatic insufficiency that may be present. Next, the chief point of attack must be the cardiovascular apparatus; and then, in advanced cases, with renal involvement, treatment may profitably be directed towards the kidneys themselves, and, lastly, as in any other disease, but particularly in so chronic a disorder as Bright's disease, much attention should be paid to the treatment of the patient, chiefly in he sense of keeping up his general nutrition, and enabling him to exercise his resisting powers to their full effect. The treatment of the gastro-intestinal disorders, in view of the protein character of the derangement, must needs vary in each individual case.

CANADA.

Personal.—Dr. Peter H. Bryce, chief medical officer for the Interior Department, Ottawa, has been in St. John, New Brunswick, where he has been selecting a site for a detention hospital, which the Federal Government will erect there at a cost of $30,000. It is expected that the hospital will be in operation by next season.

Typhoid Fever in Winnipeg.—A short time ago the city of Winnipeg appointed a medical commission to inquire into the cause of the prevalence of typhoid fever there. This committee has completed its work, and reports that in their opinion the prevalence of the disease can be laid almost wholly to unsanitary conditions prevailing in the city, which, coupled with house flies, of which Winnipeg can boast more than its proper quota, is held accountable for the epidemic under investigation.

Hospital Saturday in Vancouver.—Saturday, October 15, was "Hospital Saturday" in Vancouver, B. C. Collections were made which totaled $839.68, less than a year ago, when the sum amounted to $1,119.75.

New Wing for Hamilton, Ontario, Hospital.—The Governors of the General Hospital, Ontario, have decided to erect a new wing to the institution at a cost of $40,000. When erected the new building will accommodate 65 private patients, besides providing a modern operating room. It is likely that at the coming municipal elections a by-law will be submitted to the ratepayers for raising $50,000 for the purpose.

Graduation Exercises at the Toronto General Hospital.—The Toronto General Hospital Training School for Nurses held its annual graduating exercises on the evening of the 21st of October, when thirty-two nurses received their diplomas, eighteen of whom have already received appointments in other hospitals. The lady superintendent in presenting the twenty-third annual report stated that during the past year 625 applications for admission had been received. Forty-two of these were accepted on probation and twenty-seven were enrolled as nurses. At the present time there are four probationers in the hospital, 76 undergraduates and seven graduate nurses, making a total of 87, which constituted the nursing staff of the hospital. The total number of nurses who had received their diplomas in this school was now 407. Dr. Fred. LeM. Grasett delivered the address for the medical staff, Sir William Meredith presented the diplomas and Dr. Charles O'Reilly, the Superintendent, distributed the prizes.

Consumption of Spirits in Canada.—In Canada the consumption of spirits during the last fiscal year amounted to 5,343,954 gallons, or .958 gallons per head of population. This is the largest consumption on record since 1885. Then it reached 1.126 gallons per head. Last year the consumption of beer was 27,608,510 gallons, an average of 4.918 gallons per head of population. The use of beer has been steadily on the increase since 1869. The consumption last year was the largest on record, except the year 1902, when it reached 5,102 gallons per head. The average since 1869 was 3,182 gallons. The consumption of wines remain about the same, 0.96 gallons per head. The average quantity of tobacco used per head per year has been 2.178 pounds for thirty-five years. Last year it reached 2.765, the largest on record.

GENERAL.

American Journal of Urology.—The first number, October, 1904, of *The American Journal of Urology*, published by the Grafton Press, New York, and edited by Dr. Henry G. Spooner, of New York, has been received. Articles by Dr. Howard Kelly, of Baltimore; Dr. Winfield Ayres, of New York, and Dr. Ferdinand Cathelin, of Paris, all eminent in the field of genito-urinary diseases, constitute the leading features in this number, together with a liberal number of abstracts of interest to genito-urinary specialists. The fact that the American Urological Association and several other genito-urinary organizations have appointed this journal as their official organ, assures us that it will be a valuable addition to medical literature. The editorial board consists of the following well-known physicians: Arthur Bevan, M.D., of Chicago; Follen Cabot, M.D., of New York; A. E. Gallant, M.D., of New York; Orville Horwitz, M.D., of Philadelphia; Howard A. Kelly, M.D., of Baltimore; Gustav Kolischer, M.D., of Chicago; Robert T. Morris, M.D., of New York; William H. Porter, M.D., of New York; Robert Bruce Preble, M.D., of Chicago, and Hugh H. Young, M.D., of Baltimore. The magazine, in addition to its worth from a medical point of view, is handsomely gotten up, and taken altogether is a credit to both editors and publishers. There has long been a demand for an exclusive genito-urinary journal, and if the standard which characterizes the first number is continued *The American Journal of Urology* will be considered the leading organ in this field in America. The subscription price is $3 a year; $3.50 for foreign countries.

Mississippi Valley Medical Association.—The officers elected at the Thirtieth Annual Meeting of the Mississippi Valley Medical Association, held at Cincinnati, Ohio, October 11-13, are as follows: President, Bransford Lewis, M.D., St. Louis; First Vice-President, Frank Parsons Norbury, M.D., Jacksonville, Ill.; Second Vice-President, J. H. Carstens, M.D., Detroit, Mich.; Secretary, Henry Enos Tuley, M.D., Louisville, Ky.; Assistant Secretary, John F. Barnhill, M.D., Indianapolis, Ind.; Treasurer, S. C. Stanton, M.D., Chicago, Ill. Next place of meeting, Indianapolis, Ind., October, 1905.

OBITUARY.

Dr. Montefiore Levi Maduro, of New York, died in St. Luke's Hospital on Saturday as the result of internal injuries received six years ago in a bicycle accident in Central Park. Dr. Maduro was born at St. Thomas, Danish West Indies, and was educated at the College of Physicians and Surgeons, and in London, Paris, Vienna and Berlin. He was at one time on the house staff of Lebanon Hospital and visiting physician at Mt. Sinai Hospital. He was a member of the American and State Medical associations.

Dr. Oliver Soper, of Upper Montclair, N. J., was stricken with paralysis while at breakfast on Saturday after returning from an early professional visit. He died late in the afternoon. He was born in Lodi, Bergen County, N. J., sixty-one years ago. He studied medicine while he was a blacksmith. For thirty years he practiced in Lodi. He moved to Montclair in 1892.

Dr. Truman E. Parkman, a physician and surgeon who had practiced his profession in that vicinity for fifty years, died at his home in Rock City Falls, October 24, aged eighty-three years.

Dr. William C. Flowers, of Cambridge, Mass., died October 20, aged seventy-nine. He was formerly one of the best known physicians and surgeons in Cambridge. He was born in Halifax, N. S.

Dr. Samuel W. Woodhouse died suddenly in Philadelphia on October 23, aged eighty-three. He was one of the oldest graduates of the University of Pennsylvania. He was surgeon at Fort Delaware in 1854, at one time physician to the almshouse and penitentiary, and accompanied the Sitgreaves-Zuni expeditions to New Mexico and Central America.

Dr. George Purviance, Assistant Surgeon General of the United States Marine Hospital service, fell or jumped from a fourth story balcony of the Orthopedic Hospital in Philadelphia on October 19, and died a few minutes later. Dr. Purviance was suffering from a nervous trouble, and had been in the hospital since August. He was sixty-three years old. After practising for a time in Pittsburg he entered the Marine Hospital service in which he served more than thirty years.

Dr. Auguste Frederic Muller died in Germantown, Pa., October 20, aged sixty-four, after being ill for a long time with cancer of the stomach. Dr. Muller was chief of staff of the Germantown Hospital, and one of the most prominent physicians in that part of the city. He was born in Alsace-Lorraine, tought in the Civil War, and acquired a taste for the physician's calling while in the hospital recovering from a wound. Later he was made librarian at the Pennsylvania Hospital, and finally studied medicine.

CORRESPONDENCE.

OUR LONDON LETTER.

(From our Special Correspondent.)

London, October 15.

A FRENCH MEDICAL PILGRIMAGE TO LONDON—THE OPENING OF THE MEDICAL SCHOOLS—AN ANGLICAN CANON ON THE CLERICAL AND MEDICAL PROFESSIONS.

In the medical world of London the past week has been given up to the entertainment of a band of French medical pilgrims, numbering about 150, who, greatly daring, braved the terrors of the Channel and the horrors of our British fog in order to see something of what is being done on this little island for the cure of disease and the discovery of new truths likely to be beneficial to mankind. The visit, in spite of difficulties inevitably attending the organization of such things, went off very successfully. A liberal discount must, I suppose, be made from the glowing eloquence with which the Frenchmen expressed their admiration of all they saw in hospitals and laboratories, but as far as could be judged, they were genuinely pleased with their reception. Professor Poirier, who was one of the most prominent speakers at the various banquetings and other entertainments held in their honor, has confided to a French journalist that "this visit will be to us a profitable and imperishable memory. All we have seen in London is worthy of admiration—the cheerful aspect of the sick wards, which are adorned with flowers, and made gay by the flitting bright pictures of those graceful blonde nurses; the magnificent results of an individual initiative such as we have not made the most of in France. I leave England enchanted with my too brief visit." On the other hand our people were well satisfied with their guests. The idea of the pilgrimage originated with Dr. Sillonville, who, as usually happens in such circumstances, was less *en evidence* during the visit than any other of the band. In his student days he worked in England, and for the last ten years he has visited London every winter. He was struck by the comfort of the wards in the hospitals, by the great care taken of the patients, by the excellence of the nursing arrangements, and also by the skill displayed by the physicians and surgeons. But he was also struck by the absence of French medical students from the wards. This made him ponder over the question. Science is now the same in every civilized country. Discoveries made in Paris, London, or Berlin are immediately known the world over; but there were practical hints to be obtained by a personal visit that could never have been obtained otherwise. Several years ago he first suggested that French medical students should visit London, and he continually urged upon them the value of the experience they would obtain. There was at that time not much enthusiasm for the scheme. They thought there could not be much to learn, and "we do not know English" was a standing objection. He endeavored to meet this objection. Six years ago he organized classes for the teaching of English at the various hospitals, and evening classes were established for house physicians and surgeons. They met together and translated articles published in the *British Medical Journal*, and many medical textbooks, in order to obtain a good grasp of the technical terms. Then came the Entente Cordiale, and finally a very large number of the young men who had obtained a valuable knowledge of English accepted this proposal, and the present visit was the result. One hundred and fifty came, but there might have been three hundred. Asked what part of hospital work had struck the visitors most forcibly, Dr. Sillonville said that many things had impressed them, but perhaps none more so than the excellence of the nursing staffs. The nurses of the Paris hospitals are not so good, and the importance of this cannot be overestimated. A physician or surgeon can give directions for treatment, but he can be with a patient only for a few minutes of the twenty-four hours, and the rest of the time the patient is in the care of a nurse. Necessarily, then, for efficiency a capable staff of nurses is imperative. Dr. Sillonville sincerely hoped that the visit would be the commencement of much intercourse in the future between medical men of both countries to their mutual advantage. They had much to learn from each other, and they were all delighted at the prospect of a visit of British medical men to Paris. From many other sources it may be gathered that one of the things that most impressed our visitors was the English nurse.

They were struck by the high standard of the nursing staff at every hospital which they visited. All the nurses seemed to them to have the air of ladies; most of them were clever and many of them were beautiful. Then the wards struck them as brighter and cosier than those of the Paris hospitals. In fact, in some places they were inclined to think the comfort was rather overdone. From the scientific point of view one of the things that most interested them was the Pathological Laboratory of the London County Council Asylums, which is under the direction of Dr. Mott. Here the brains of deceased lunatics at the eight great asylums of the County of London are examined and classified. Dr. Mott exhibited the classified collection, and pointed out that the brain was as characteristic of the individual as the face. Among the brains was the smallest specimen of an adult human brain known to exist, and Dr. Mott pointed out that the brain of a chimpanzee was of a higher type than those of many lunatics. The brain was not unlike a large walnut—the skull corresponding to the shell, the dura mater, pia mater, and arachnoid membrane to the skin, and the brain substance itself to the nut. One important result of the work of the laboratory had been that dysentery, which for long had made fearful ravages in the asylums, was proved to be an infectious disorder; the segregation of the patients which resulted from this discovery produced a great saving of life. One great disadvantage from which this splendid laboratory suffers is its situation many miles out of London amidst the Essex marshes. Many of the visitors expressed surprise that so important an institution should be buried away in the country instead of being made accessible by being placed in the metropolis. This view has frequently been expressed before, but the County Councillors turn a deaf ear to all representations on the subject.

If it be true that blessed is he that hath his quiver full, it may be said that London rejoices in a perfect benediction as far as medical schools are concerned, for she has eleven. These were opened last week for the winter session with the usual blare of oratory. The homilies were for the most part of the usual character—variations on the eternal text "Be virtuous and you will be happy." In one or two of them, however, the speaker departed somewhat from the well-beaten track. Sir William Macewen, of Glasgow, who delivered the Huxley Lecture at the Charing Cross Hospital, spoke in defense of the appendix against which a war of extermination was now being waged in some quarters. "Some surgeons," he said, "have freely admitted that when making an incision in a patient for some other disease they frequently remove the little organ as a precaution against appendicitis." But is the appendix, he asked, entirely useless to man? Some contended that the small intestine could be done without, that the spleen was superfluous, and that the stomach itself could very well be dispensed with simply because some people had lived after these organs were removed. Sir William drew a fanciful picture of a future race in whom the whole digestive apparatus would be removed, and also would retain but a small incision, down which could be dropped concentrated tablets of nourishment. "All that would be necessary," he continued, "would be for a firm of chemists to enlarge its premises, and the tablets could be delivered every morning by the postman. No navy would be needed to protect our sources of food supply, and the domestic servant problem would be solved forever." Macewen holds that the appendix itself has an important function in assisting digestion. Moreover, it is the chief habitat of a certain micro-organism that is most useful in attacking imperfectly assimilated nourishment, and if only as a medium for the cultivation of these bacteria the appendix has its useful mission to perform and should be retained. The address may be regarded as a counterblast to Metchnikoff's suggestion that old age may be prevented by the removal of the large intestine.

At St. Mary's Hospital, Dr. A. E. Wright, who is chiefly known to fame as the inventor of a method of inoculation against typhoid fever, the value of which is now under consideration by a Special Committee appointed by the War Office, deplored the want of interest in research shown by his fellow countrymen. He said it was doubtful whether among the forty or more millions of the British race a hundred scientific workers were actively and continuously engaged upon the problems of disease. Here and there an isolated worker was to be found devoting to the work of medical research such free time as he might have at his disposal, but practically no organized effort was in existence. The cause was, according to Dr. Wright, easy to discover. It was a question of financial necessity. Not only was there nothing in the form of reward for successful solution of the problems of disease, but the worker who devoted himself to the task of solving this, the outstanding problem of civilization, immediately found himself face to face in his own person with problems of the primitive savages, those of finding subsistence, and clothing and shelter from the weather. His solution was the provision of salaries on the scale of those which obtained in civil or other Government services. A sufficient beginning would be made by the annual allotment of even so small a sum as was paid to the State in the form of death duties from the estate of a single millionaire. This would provide an average income of £500 for 100 workers, and would probably leave over a sufficient balance for the upkeep of the necessary laboratories.

The London School of Tropical Medicine is, of all our institutions, the one in which the intelligent visitor finds the most striking embodiment of the imperial idea. At the opening of the winter session the place swarmed with ex-Governors of Colonies, the proconsuls of the British Empire, and in the wards and laboratories are seen the men who are about to go forth to these distant lands as missionaries of health and civilization. Sir Patrick Manson, who spoke after the delivery of an inaugural address by Sir Charles Bruce, formerly Governor of Mauritius and several other colonies, also deplored the want of funds available for the furtherance of medical research. He said that it had come to be recognized that the great causes of disease in the tropics were not bacteria but protozoa and larger parasites. These, he pointed out, had never been adequately studied in England; the most important information on the subject had been gathered from France and Germany. There is not, said Manson, with sorrowful emphasis, a single man of English nationality who is a competent protozoologist or helminthologist. The Government has promised a grant of $2,500 a year for five years for the endowment of a worker on protozoology, and Manson appealed to the public for an equal sum to be devoted to the study of helminthology. Unfortunately the British public cares nothing either for worms, except as bait for fish, or for protozoa.

At the School of Medicine for Women, Miss Murdoch complained that the unthinking world has adjudged the whole body of medical women as frumps because a few have been careless of their personal attire.

As a fact, she said, many of the graduates dress well and look well. To this it may be replied that it is also a fact, painful though it be to admit it, that there are many women graduates and students who do neither. Short hair and general dowdiness are still the badge of a considerable proportion of their tribe. But it is pleasant to hear one of their leaders denounce frumpishness. Miss Murdoch made the general statement that most women wear too much. "Three layers," she said, "including the dress, seem to me all that is necessary, though I have counted as many as twelve."

At the annual dinner of the Norwich Medico-Chirurgical Society, Canon Jessopp, a cleric who has won considerable distinction in literature, confessed that when at the age of twenty-three years he had charge of a parish he had practised the art of healing by the light of Nature after a somewhat heroic fashion. He had given calomel in 12-grain doses, had cut blisters (*sic*) off an old woman's breasts, and had done all sorts of operations. He looked back with horror at these proceedings and was thankful that he had escaped trial for manslaughter. Perhaps it was owing to this experience that he had been saying for many years that the medical profession was the grandest in the world. To begin with, he said, the preparations for it were incomparably superior to those required for entering any other profession. When he considered the course through which every medical man had to pass before he was qualified to practise it filled him with admiration and also with a certain amount of shame and certainly of regret. He was afraid examinations through which the men of the clerical profession had to pass before they were qualified to teach and preach and exercise their functions were less severe than they used to be. While the medical profession had been going up the clerical had been going down. The estimation in which medical men were now held was immeasurably higher than it used to be when he was young. The Canon went on to say that the hope of civilization, of the happiness of the human race and of progress in all directions lay with the doctors who were pushing forward their discoveries every day. Sir Arthur Conan Doyle, M.D., the creator of Sherlock Holmes (the idea of which character he got from Joseph Bell, one of his old Edinburgh teachers), who was present, indulged in some amusing reminiscences of his short career as a medical practitioner. When he was in America he remembered an American being kind enough to take the chair at a little dinner at which he was present; and in proposing his health he said it was a sinister fact that although Conan Doyle was said to be a doctor, no living patient of his had yet been seen. Doyle went on to say that few medical men had seen so many sides of the profession as himself. In his short and checkered career he had served as a surgeon in a whaling ship; he had been in South Africa as an army doctor; he had practised in the country, and in the slums of a great city. He had even attained the dignity of a consulting room in Wimpole Street—one of the thoroughfares in this metropolis in which doctors most do congregate. This referred to the fact that he had tried consulting practice as an ophthalmic surgeon. Patients did not come, however, and he soon found his true sphere in literature. "One conviction," he proceeded, "has always remained with me, and that is that whatever line of life a man goes into, as long as he is to use his brain the medical training is absolutely the best training a man can undergo. There was a time when a young man who was going to do anything in the world was passed mechanically through the bar. I believe the time will come when the similar young man will be passed through medicine, because I know no other means by which he could get to the fundamental and absolute facts of life. The mere fact that in his training a man has to undergo so searching an ordeal in the most critical years of his life, and pays such enormous attention to detail, is in itself evidence that he receives a splendid training. I have always said that a man who has mastered Gray's Anatomy, to him life has no future terrors. If our young army officers had five years' study in the same sense that the young medical man has five years' study we should become the terror of Europe."

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Fifty-fourth Annual Meeting, held at Pittsburg, September 27, 28 and 29, 1904.

THIRD DAY—SEPTEMBER 29.—*Continued.*

(Continued from Page 763.)

Brief Remarks Regarding the Home Modification of Milk.—Dr. Theodore J. Elterich, of Allegheny, presented this paper, the object of which was to emphasize a few general truths regarding the home modification of cow's milk, without attempting to cover the work which has been done in this direction, not to criticize the various methods in use at the present time. According to the method used by the author, the percentages of the proteids and fat, very low at first, are gradually increased until they approximate the averages required at the end of the first year. The quantity for each feeding depends upon the age of the child, and the table recommended by Holt is usually followed. An accompanying weight-chart of a patient suffering from malnutrition is a fair indication of the results obtained in the majority of cases.

Observations on Food in Typhoid Fever.—Dr. James I. Johnston, of Pittsburg, said, that in the management of typhoid fever the attention should be directed primarily to the nursing, care of the patient, efficient hydrotheraphic measures and to proper feeding; secondarily, to the employment of drugs, usually for the relief of symptoms. He discussed the question of food about which there is diversity of opinion, and quoted the case of Dr. Stuart Patterson, of Pittsburg, in which the patient had no food for twenty-one days—water only being given. The course of the disease was very favorable and the loss of flesh and strength were no more marked than is usual. While not agreeing entirely with those who would give no food during the period when desire for it is absent, Dr. Johnston has restricted his patients at this time of the disease very greatly, and in a study of some fifty cases he thinks he has seen some advantage, at least in comfort to the patients, when compared with fifty other cases treated immediately preceding this group. In the class of cases in which limited feeding was employed during the period of anorexia the cases were less toxic, were no more emaciated than other cases, and made a quicker convalescence. There were but three cases of relapse, no perforations and few hemorrhages. All had flat abdomens, one only required treatment for tympanitis, and few any treatment for diarrhea other than stopping nourishment for a brief period.

The Influence of Milk Infection Upon the Course of Acute Infectious Disease in Adults.—Dr. David L. Edsall, of Philadelphia, reported a large series of cases of typhoid fever occurring in one hospital ward and under entirely similar conditions, excepting for a difference in the care of the milk in the two periods contrasted. When the service began a very large proportion of the cases had severe diarrhea and many had mild diarrhea, while abdominal symptoms that were frequently very distressing were strikingly common. The milk was suspected to be at fault, and bacteriological examinations showed extremely large numbers of bacteria. The milk was Pasteurized after this, and in the following three and a half months of the service, diarrhea was almost absent and abdominal symptoms were extremely slight and were uncommon in the group of cases as a whole, the milk evidently having produced the diarrhea and the severe abdominal symptoms in the earlier cases, and probably having been largely responsible for several deaths. The milk supply was subsequently changed and is now under careful regulation and it seems in all ways satisfactory. The great importance of determining definitely in both private and hospital practice that the milk comes from an approved source and is properly cared for was emphasized, as well as the fact that such conditions, while not common in such widespread epidemic form, are still undoubtedly common in individual cases; and a bad milk probably exercises not uncommonly a very evil influence upon the prognosis of acute infectious diseases. Milk infection of this kind is peculiar from a clinical standpoint, in that it is observed in patients already ill. The milk infection is very likely to be overlooked, because the symptoms may readily be attributed to the primary disease.

Dr. Adolph Koenig, of Pittburg, in the discussion said, he believed that physicians should be guided largely in their efforts to cure disease by paying attention to the natural instincts of their patients. He believed that it was an established physiological fact that there is no digestion of food possible when there is a temperature of 102° F., although he is not in a position to verify it. He has withheld food, absolutely everything, but a little whiskey for sixteen days, with the most happy results. As soon as the patient manifests desire for food, he believes that milk is the best diet and the best results are to be obtained by adding barley water.

Dr. Stengel, of Philadelphia, considered the doctrine of overfeeding a most pernicious one, and one in which he had seen the most disastrous consequences. While he could not bring himself to withhold food as Dr. Koenig suggested, during the period of anorexia, still he is convinced that in the first period of the disease, nine out of ten are overfed.

Section B.

Paraffin as a Surgical Medium.—Dr. M. Delmar Ritchie, of Pittsburg, recommended the use of cold solid paraffin of a melting point of 110° F. injected by means of a lever injector. He stated that the production of an embolus was impossible when cold, sterile paraffin was injected into the surgically cleansed tissue through the rounded needle point, and that there was no known danger to life in the correction of any deformity, however marked.

Dr. Stewart L. McCurdy, of Pittsburg, felt that the employment of cold paraffin would be a great advance over the old method of employing the heated article which had been followed in almost every instance by some complication, such as ulceration or hyperemia.

Dr. Dillinger referred to a case of total blindness caused by the paraffin getting into the central artery of the retina, which he felt was probably due to semisolid or hot paraffin being used, and that much of this objection would doubtless be removed by the method suggested by the author.

Dr. Shirls B. Jackson, of Pittsburg, stated that he also had seen a case of embolism of the retinal following the employment of this remedy, and believed it was better to leave the work to those who had considerable experience in it.

Clinical and Statistical Study of Convergent Strabismus.—Dr. Wendell Reber, of Philadelphia, gave a critical review of 36 private patients and 130 hospital cases, being classified according to sex, age of onset, determining influence, degree of deviation, amblyopia, increase in vision, variety of squint, and refraction. The treatment and the results obtained in each case were carefully outlined, those patients above the age of seven being contrasted with those below that age. In conclusion, he stated that he believed heredity played an important role, and urged the early treatment of all cases occurring before puberty with properly adjusted glasses.

Carbolic Acid and Ammonia Burns of the Eye.—Dr. Edward Stieren, of Pittsburg, called attention to the great dearth of information in ophthalmic literature on the action of ammonia on the tissues of the eye, and stated that eyes so affected almost invariably are rendered blind by dense opacity of the cornea. The essayist reports four cases of ammonia and three cases of carbolic acid burns of the eye, and remarking on the similarity for the first few days of the ocular reaction to these agents, and the great dissimilarity in the ultimate outcome, those burned by ammonia recovering with very poor vision or no vision at all, while the carbolic acid burned cornea clear up and in time recover their former transparency.

Mastoiditis.—Dr. Fremont W. Franhauser, of Reading, considered the condition with reference to the etiology, pathological changes, symptoms, diagnosis, prognosis and treatment. He urged careful examination in all suspected cases, with operation, being sure to make the opening large enough, if no improvement occurs within a short time, believing if the operation was not complicate, there was very little danger and that it was better to sacrifice some parts to early operation than to allow the grave conditions to continue, and thus run the chance of losing a valuable life.

Retarded Development of Speech in Young Children.—Dr. G. Hudson-Makuen, of Philadelphia, after explaining some of the frequent causes of faulty speech development, such as structural irregularities in the peripheral organs, obstructed nasal respiration and paretic conditions of the nerves supplying the tongue, palate and lips, dwelt particularly upon disturbances of hearing as a factor in the causation of the various forms of defective speech, and of the effects of faulty hearing and faulty speech upon mental development. He said, that if a child does not hear words spoken he will not understand them, and if he does not understand them he will not use them, and that the intellectual centers being deprived of the stimulus which comes from the use of spoken language will share in the retarded development, and the result will be a feeble minded as well as a deaf

child. The cause of the condition may be by no means difficult to determine and the diagnosis and prognosis are equally difficult, and thus it happens that children who have no organic defect of the brain, but who have failed to develop intellectually because they are hard of hearing and cannot talk, may find their way into institutions for imbeciles and idiots because of mistake in diagnosis. Partial deafness in young children or deafness for only a few sounds is sufficient to interfere with the normal development of speech, and the child failing to understand general conversation gradually stops listening, and the brain finally loses its power to comprehend the meaning of spoken language. Dr. Makuen suggested in addition to the usual and well-known methods for improving the peripheral auditory apparatus, a course of training for the development of the central perceptive faculties by regular systematic training and education. He said, that children are sometimes intellectually deaf and the treatment for these cases consists in the frequent repetition of words in more or less close approximation to the ears, after the manner first suggested by Urbantschitsch, of Vienna. An interesting case was reported, illustrating the various points in the paper, of a child who had been born deaf and dumb, and who had actually been taught to hear and speak by this treatment.

Suprarenal Gland in Surgical Shock.—Dr. Alex. R. Craig, of Columbia, described two cases. The first was a compound fracture of the elbow caused by a gunshot wound six hours before his admission to the hospital, at which time, he was pulseless, cold, cold sweat, pupils dilated and labored breathing. The injection of three pints of normal solution, in the first and third of which was one dram 1 to 1,000 solution of suprarenal extract was followed by a very favorable reaction. The second case was a compound fracture of the skull in the right parietal region, caused by being thrown from a freight train, in which case similar results were obtained.

Boils.—Dr. George W. Guthrie, of Wilkesbarre, said that boils are caused by infection of follicles of the skin by pyogenic bacteria; the same laws govern their growth and development, as in the cases of the most serious infective inflammation. There are several predisposing causes: coarse, unclean skin; large follicles; slight traumatism of the surface; anything that lowers the vitality; overwork, poor food, exhausting diseases, fever, albuminuria, diabetes. Under treatment, use whatever builds up the general system: proper hygiene, needed rest; also pay attention to the skin; as medicine, quinine possesses decided power in preventing pus formation. Abortive measures are of doubtful efficacy, and unwise meddling often causes much more harm than good.

Clinical Studies in Blood-Pressure and Shock in Traumatic Surgery.—Dr. Jonathan M. Wainwright, of Scranton, stated: (1) That there is one drug, morphine, of which the value is unquestionable. (2) The most effective treatment is the mechanical one, which suffices alone in many cases, and after it has been carefully applied, strychnine and digalin may possibly be of value. (3) Nitroglycerin, atropine and alcohol are inert or harmful, though alcohol is valuable in after condition. (4) Intravenous infusions are of real and great value. The efficiency of adrenal, in addition, is doubtful. The author also showed a series of charts illustrating the conditions of various patients.

Craniectomy in Microcephaly.—Dr. W. D. Teagarden, of Washington, recommended in the case of a child with a fairly nourished body and symptoms of cerebral irritation, the operation be performed as soon as possible after the minimum age, *i.e.*, nine months has been reached, believing the sooner the operation is performed the better, and that the mortality from shock will be small, if performed at that time, as compared with those cases in which it is done after emaciation has begun and the nervous system weakened by constant irritation of the nerve centers, reporting a case in which the early operation had seemed to be of great advantage.

Dr. Theodore Diller, of Pittsburg, felt that the theory upon which this remedy was based *i.e.*, that the sutures of the skull would not permit to expand and this prevented the development of the brain, was an erroneous one, and did not favor the operation.

Dr. T. H. Murdoch, of Hope, who for a number of years has had charge of the Western Pennsylvania Institution for Feebleminded Children, stated, that there were in that institution a number of children who had been operated upon without any apparent results, and believed that the supposed advantage accruing by opening the skull would be more than counterbalanced by the growth of cicitrical tissue.

Brain Tumor and Trauma.—Dr. Edmund W. Holmes, of Philadelphia, stated, that the pathology of these growths is not different from those in other parts of the body, and that with the exception of cysts, sarcoma and gumma are the most frequent. The upright posture renders the cranium more liable to injury, and in severe cases the diffusion of the force increases the dangers to the brain. The direct influence of the blow is how by the tumor appearing at the seat of the injury, the most vulnerable parts of the brain being, therefore, the most subject to tumor, although by reason of concussion and contercoup deeper parts may be affected. The fact that the brain is so well protected from without against infaction, so long as its outworks, the scalp, the skull and the meninges are intact, militates against the bacterial origin of tumor and favors the belief in the cellular, nutritional and formative elements as causes of the growth.

Acute Gastric Dilation.—Dr. Theodore B. Appel, of Lancaster, reported three cases of this condition; the first being that of a male seventeen years of age, who had sustained a fracture of the left femur by a bank caving in on him; the second case was that of a woman, forty-two years of age, and followed four days after an operation for fixation of the left kidney; the third was that of a male, twenty years of age, neurotic, and with a marked history of catarrhal gastritis, who after about a week's illness following indiscretion in diet, associated with alternate diarrhea and constipation, abdominal pain, subnormal temperature and rapid pulse, followed about an hour afterward by a rectal hemorrhage of a quart of blood, which was succeeded by vomiting. The first two cases terminated fatally, and the last recovered. Absolute rest to the stomach, relief of distention of the stomach, rectal feeding and strychnine hypodermatically were recommended.

The Cause of Death in Operated Cases of Intestinal Perforation Occurring in Typhoid Fever.—Dr. J. Hartley Anderson, of Pittsburg, reported twenty-one laparotomies, one being for typhoid appendicitis with peritonitis; another of peritonitis from infection of the mesenteric lymph gland; and another to obstruction due to a mass of round worms in

the ileum. He described, in detail, the operation, and stated as the primary causes of death following, 1, shock; 2, toxemia of peritonitis; 3, devitalization of the body by fever. He contrasted the value of local and general anesthesia, and called particular attention to the danger from toxemia from the contents of the paralyzed bowel.

Cæsarean Section.—Dr. G. W. Wagoner, of Johnstown, reports history of a Slavish woman, aged thirty-four years, who when admitted to the hospital, after being several hours in labor and unsuccessful attempts to deliver her, presented the following condition: all parts normal; os fully dilated, child presenting transversely with the right shoulder impacted in the superior straight, and the right arms prolapsed, pains frequent and excessively strong. After repeated unsuccessful attempts at version under complete anesthesia, rupture of the uterus seeming imminent, Cæsarean section was performed, following which the patient progressed favorably and was out of bed on the twenty-sixth day.

Congenital Elongation of the Left Lobe of the Liver.—Dr. Levi J. Hammond, of Philadelphia, reported the case of a woman, thirty years of age, who had suffered for eight years with pain, pulling and pressure in the epigastrium, worse when lying down on the back. At operation, the left lobe of the liver was found to be extended entirely across the lesser curvature into the left hypochodrium, which was flattened out at the extremity over the spleen. This elongated lobe was sutured to the abdominal wall, and this was followed by an uninterrupted recovery.

On the Advantages of Performing Capital Operations in Certain Cases Without Anesthesia.—Dr. J. J. Buchanan, of Pittsburg, gave the following indications for the performance of operations without anesthesia: (1) Profound septic infection; (2) severe collapse from loss of blood and shock; (3) fecal vomiting with liability to drowning during operation of aspiration pneumonia subsequently; (4) collapse or compression of lung with liability to respiratory failure; (5) obstruction of esophagus; (6) advanced kidney disease with liability to anuria; (7) case of performance with minimum of pain. He gave an extensive list of operations he had performed in the presence of these indications, without anesthesia, including laparotomies for appendicitis, intestinal obstruction, visceral exploration, colostomy and intraperitoneal abscesses; amputations of thigh, leg, arm and forearm; ligature of arteries for aneurism; craniectomy for depressed fracture of the skull; wiring fractures patella by open incision; operations on chest wall, trachea, perineum, prostate and bladder; herniotomy for strangulation; operations for radical cure of hernia and intestinal resection. He emphasized the comparatively slight pain usually produced by even formidable operations and the great tolerance and cooperation of the patients, even children, foreigners and delirious patients. He stated that the surgeon should always have sufficient reason for withholding the anesthetic and should always secure the cooperation of the patient if he be of a reasoning age. No restraint is necessary or should be employed. Promise of anesthetic should be given if pain should be beyond endurance. Fulfilment of such promise is rarely required.

Professional Responsibility in Accident Cases Involving Litigation.—Dr. John B. Roberts, of Philadelphia, stated that the experience of the public had caused a justifiable distrust of surgeons employed by corporations as well as of experts paid by patients endeavoring to recover damages. Medical men could do more than other citizens to dispel this doubt as to the reliability of professional testimony. The duty of the medical attendants employed by the party sued, and that of the doctor of the patient injured are identical. The duty of each is to obtain promptly a return of health and a just settlement of the claim. Many unjust verdicts against railroads and other corporations are due to the patient becoming neurasthenic or hysterical because of the unwise, ignorant or dishonest suggestions of attending physicians, lawyers and friends. Immediate and careful examination, accurate record of the patient's statements and the symptoms at the time of injury, the avoidance of injurious suggestions with prompt institution of scientific treatment, and an early settlement of damages will diminish litigation and hasten the recovery of the patient. The doctor should make several examinations. He should remember that disease may exist before injury; that disease may follow injury, and yet, not be due to it; that the patient may be mistaken, and not dishonest, and that hysteria and neurasthenia are common conditions, existing sometimes with organic lesions without being connected with these lesions. Dr. Roberts believed that corporations liable to be sued would save money by always employing experienced practitioners to examine the injured patient early, in company with the medical attendant, and by insisting upon at least two such examinations. Delay in settlement, too many examinations, unwise suggestions of friends and numerous conferences with lawyers are often productive of traumatic neuroses, and have unjustly drawn thousands of dollars from corporation treasuries.

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

Section on Tropical Medicine.—*Continued.*

(Continued from Page 768.)

The Anti-Malaria Experiment at Mian Mir.—Ronald Ross, Professor of Tropical Medicine, University of Liverpool, said that the anti-malaria experiments at Mian Mir has been described in three reports, namely, one by Stephens and Christophers, one by James, and one by Christophers alone. The first, apparently written early in 1902, deals merely with some preliminary thoughts and observations, and he therefore did not propose to examine it here, beyond remarking that it clearly defines the object of the experiment which was then about to commence. That object was "to demonstrate by test operations" the "utility of all anti-malarial measures," particularly the destruction of *Anopheles* larvæ. The actual operations and their results are detailed in the subsequent reports of James and Christophers; and with regard to those, he made the following criticism: (1) The profession is not convinced that mosquito propagation at Mian Mir was really suppressed to the extent claimed, even over the small radius of half a mile; (2) the test employed for detecting reduction in the number of mosquitoes consisted of nothing but the formation of a personal impression unsupported by definite figures, and was therefore neither delicate enough nor convincing enough for the purposes of a formal and important experiment like this one; (3) the figures given regarding variations in the amount of malaria are not sufficient to enable one to form any

opinion one way or another; (4) several of the statements contained in the reports appear either to be contradictory or unintelligible, or to involve mechanical impossibilities; (5) even if we admit the thoroughness of the work done and the validity of the tests used, the whole experiment is still open to the final criticism (*a*) that it might not have been continued long enough, and (*b*) that the radius of operations might not have been large enough. He therefore thinks that the sweeping conclusions placed at the end of Lieutenant Christophers' report are not supported by the evidence which he and Captain James have published. They are not entitled to claim any more than is contained in the following sentence: "That after operations extending to a half-mile radius, lasting a year and a half, and (apparently) costing between two and three hundred pounds, no very large reduction in the number of mosquitoes or in the amount of malaria was, judging wholly by their own personal impressions, effected." Owing to the omission of a financial statement for 1903, one can only estimate the cost given above. The considerable sum spent on bricking the watercourse is not included, as it seems to have been more or less useless; probably a few pounds' worth of oil would have done as well. In these remarks he has confined himself to a textual commentary and has not dealt with the broad principles which govern the prophylaxis of malaria, and which, though self-evident enough, require a more or less mathematical treatment for their formal demonstration. The logical basis of the great measure of mosquito reduction is absolute. There is no doubt whatever that in any locality one can reduce mosquitoes to any percentage one pleases, provided their propagation is arrested to a sufficient degree and within a sufficient radius. This proposition, like the multiplication table, does not require experimental proof, and is incapable of disproof. If experiments would appear to disprove it, the experiments and not the proposition must be wrong.

Experiment is required, not in support of the general principle, but only in order to obtain certain unknown constants. One still has to determine (*a*) the radius of operations required to reduce the density of a given species of mosquito to a given percentage; and (*b*) the percentage of mosquito reduction required in order to obtain ultimately a given percentage of malaria reduction. But experiments directed to this end must be of a true scientific quality; they must be prefaced by a mathematical inquiry and be executed by means of rigid tests applied by the brain as well as by the hand. In the meantime, one may rest assured that the smallest work against malaria will not be without its reward. The oiling or drainage of a single pool, the cinchonization of a single person, and the "proofing" of a single room must and will perform their small quota of good. If more than this can be done, let it be done; better results will follow. But if local authorities wish to clear the malaria in a large town or cantonment they must be prepared to spend money on the work, just as they would for a new water supply or sewerage system. The example of Ismailia is always before them. The road leads straight forward. Work like this at Mian Mir only tends to arrest enthusiasm in the cause without really adding anything definite to our knowledge.

The Results of the Campaign Against Malaria in Mian Mir.—Captain E. P. Sewell made this report in which he said that the results were not satisfactory. The causes of failure he had summarized as follows: We can only conclude that the campaign has up to the present proved a failure, and the cause of this failure is not far to seek. The operations were doubtless efforts in the right direction, but were conducted on a scale utterly inadequate to make any impression on an evil of such a magnitude as that against which they were directed. At the outset, it was a mistake to attempt to treat the R. A. lines as an isolated area. They cannot be treated as such, and any factor which affects the rest of the station is bound to affect a part of it, which is not separated by any physical division, but is in direct continuity and subject to the same influences.

Secondly, any plan which aims at the reduction of malaria in Mian Mir must have as its basis the entire abolition of the irrigation systems, and the clearing off of all watered crops in the cantonment, and around it for the distance of at least one mile.

Thirdly, although the operations included the filling up of certain pits and holes and the draining off of water from low-lying patches of ground, a few minutes' acquaintance with Mian Mir after a heavy shower of rain would convince any one of the utter inadequacy of such local measures in one corner of the cantonment. There was nothing to prevent the *Anopheles* breeding in any of the numerous pits and ditches outside the area, and flying a few hundred yards to the buildings within the area.

To meet with any success a campaign against malaria must be on a very much larger scale. Nothing short of the complete leveling and draining of the whole cantonment and its environments, and the total abolition of irrigation and irrigation channels in and around the station is at all likely to cause any appreciable difference in the amount of malaria in Mian Mir.

Unfortunately these drastic measures involve considerable expense. The stoppage of irrigation would entail great loss to the zemindars, and the compensation paid to them for the deterioration of their land and loss of crops would amount to a large sum of money, which local funds are quite unable to meet, and which the Government of India have hitherto shown no disposition to grant.

Prophylaxis Among Troops.—Andrew Duncan proposed to limit his remarks to the prevention of malaria amongst the troops in military expeditions, and more particularly to the mobile columns of the same. The preponderating effect in disablement that malaria causes in campaigns has even been manifest. It will suffice to mention as examples the Ashanti expedition of 1896, in which one-half of the troops employed were placed *hors de combat* by African remittent fever; the Spanish-American war, in which out of 13,657 men in hospitals at Cuba 2,014 were causes of malaria; whilst in our Burmese, China, Abyssinian, Looshai, Duffla, Malay, and Afghan wars, amongst others, malarial fevers either headed the list of admissions or took the second place. What, then, are the means whereby we may prevent this large disabling influence?

Before proceeding to the more especial means of prevention in accordance with the true etiology of malaria, he first drew attention to the avoidance of the predisposing elements in matters connected with: (1) The selection of the men. (2) The age of the men. (3) Race. (4) The season for operations. (5) The clothing. (6) The period of marching. (7) The campaign grounds. (8) The food. (9) The precautions at night.

Selection of Men.—First in the selection of men. Here it must be borne in mind that previous attacks of malaria render the subjects of them more prone to future attacks. Hence the medical histories of a regiment must be closely scrutinized. For example, in the Duffla expedition of 1874, the Sixteenth M.I. had for the eleven months previous to the outbreak of hostilities suffered greatly from "fever" in Assam: the

Forty-fourth L.I. had for seven months before the expedition been stationed in the malarious plains also of Assam; in the campaign the Sixteenth M.I. had 29.06 per cent. admissions for malarial fevers, the Forty-fourth Assam L.I. 18.40 per cent. for the same cause, rates far above those of the other regiments not presenting the malarious history which had admissions ranging from 3.60 per cent. to 7.35 per cent. only. Again, in the Afghan war my old regiment, the Fourteenth Sikhs, one of the finest regiments in the Bengal Army, suffered greatly from malaria; previous to the campaign they had been for three years stationed in the malaria-stricken Peshawur Valley. But not only does a malarious history predispose to malarial disease, but it also powerfully influences the onset of other diseases, especially amongst native soldiers—for example, pneumonia—it is also one of the common causes of cardiac dilatation. A regiment with a clean malarial history presents a great contrast to those cited above. I was some time in charge of the Twenty-third Pioneers, in the Afghan campaign. They had come down from the hills of Simla in rude health, and no regiment during the war gave a better medical history. Hence one learns that regiments that have suffered markedly from malaria previously should not be chosen. The severer and more fatal forms of malaria never, as a rule, attack those previously immune from it.

Age.—Regarding age, it has been found that young soldiers and recent recruits suffer more than their older comrades. This was well shown in the Ashanti expedition of 1895-6.

Race.—Respecting race, it has been found that the negro race possesses the greatest immunity; in the War of the Secession in America, negro troops suffered the least from malaria, while a like experience was obtained in the Mexican war.

Season.—As regards season, meteorological influences speak with no uncertain voice. The end of the hot season in the tropics, when great alternations between the morning and evening temperatures occur, is very predisposing to malaria; again, the most dangerous time in the United Provinces in India is at the drying up of the rains. Hence this period of the year should be avoided if possible for military expeditions. A striking example of the above facts was shown in Ashanti in 1873. Here previous to the arrival of Sir Garnet Wolseley certain military operations had been carried on in the unhealthy season of the year. The Marines became so stricken with malaria that they had to be sent home, the mortality of the strength disembarked being 17.30 per cent. Sir Garnet operated in the succeeding healthy season, and the mortality for the strength was only 3.14 per cent.

Clothing—Respecting clothing, flannel should be worn. Khaki cotton drill is not a good material to wear. At my recommendation in Afghanistan the men of the regiment were given a woolen jersey each, and the admision for malaria at once decreased. Cotton drills become damp and clammy in a humid climate. In the Perak expedition, for instance, it was a great source of fever. Flannel protects against the great alternations of heat and cold, of the day and night temperatures, inasmuch as by it a more equable temperature is insured.

Marching Periods.—As regards the period of the day for marching, some authorities, such as Morache and Sanderson, advise not to march in the early morning. The late Professor Parker recommended doing so in the afternoon in hot malarious climates. He would, however, differ from this teaching on account of the danger of sunstroke. He never observed any ill effects from marching in the early hours in Afghanistan, while the men were far more knocked up whenever they did march in the afternoon. In Ashanti also it was found that although malaria was most powerful in the early morning, yet less harm occurred when marching in these hours than when proceeding for a length of time in the sun. The men should always have a meal of coffee and bread previous to setting out, and should also smoke in moderation, as Sanderson found by experience the good effect of tobacco in warding off attacks of malaria when marching in the early morning. At the end of the march, sitting down in wet clothes should not be permitted, and arrangements should be made whereby the men always have their great-coats handy. In the Afghan war the Fourteenth Sikhs were without their great-coats, and for nearly three weeks slept on the ground with only their ordinary uniform. Malarial fever was exceedingly prevalent amongst them. The cholera belt should always be worn.

Camps.—As regards the camping grounds, the exigencies of the military operations must of course always be of chief weight. But as showing the influence of healthy camps over the reverse, it may be mentioned that during the Zulu war the second division enjoyed a high state of health, being encamped and operating on high bracing uplands. The first division, on the contrary, was on the hot swampy coast line, and suffered much from fever. The American War of the Secession gave us a striking example of this in the force occupying the Atlantic coast: where there were huge alluvial tracts the intermittent fever-rate was 194.03 per 1,000, as against 121.77 for the Pacific region, where only a narrow strip of land intervened between the sea and the mountains. Again, especial precautions should be undertaken where the necessities of warfare entail much disturbance of the soil, as in making fortified places. This was shown in the large amount of malarial fever that attacked the men in the Zulu war during the erection of Fort Chelmsford. In the French army, again, at Madagascar, the men employed in road-making died like flies.

Food.—Turning now to the food of the men, the ration must be sufficient, and it should not be a monotonous one. Livingstone in Africa found plenty of wholesome food protected his men more than quinine. Tea and coffee should be as far as possible habitually drunk, both on the march and in camp. Koch recommends that all water be boiled in the prevention of malaria. In the Niger campaign the only white officer who remained free from the disease boiled his water. The late Sir Henry Stanley used to emphasize the importance of sterilizing water in combating malaria. In the Terai the Forest Department, by constructing deep masonry wells, have enabled their employés to remain permanently at work at the station at which they had formerly to be relieved periodically every fortnight on account of the deadly malaria.

Sleeping Places.—With regard to the precautions to be taken at night: where arrangements can be made, the men should not sleep on the ground. In the Spanish-American war it was reported that "nearly all those who slept on the ground after the battle of July 1 to 3 contracted some form of malarial fever, the worst cases being in those who had to sleep on wet ground with only their army blankets for bedding. Every one of a number of men who slept on wet ground at a certain spot near 'Bloody Bend' died later of pernicious malaria." Mr. Sanderson, whose life was spent in the jungles of Chittagong after elephants, attributes the fact that he was remarkably free from malaria to two facts: (1) that he always slept off the ground on a bedstead, and (2) that he always slept within mos-

quito nets. This last fact brings us to the methods by which we may attack the *fons et origio mali.* Malarial fever may be prevented in three ways: (1) by malarial protection against the infected mosquitoes; (2) by destruction of the infected mosquitoes; (3) by prophylactic drugs.

Mechanical Protection.—With regard first to mechanical protection: any one who has been on a campaign must recognize the fact that for an army on the march, protection by mosquito nets is out of the question. What chance would there be for the net remaining intact during the daily packing and unpacking of the impedimenta. Again, in these days, when one's luggage is cut down to a minimum, so that a tent and portable bedstead are even out of the question, how could a mosquito net be fixed up? The officers of the force might, perhaps, arrange for such, but does any one imagine that Tommy Atkins would take care of his net? The destruction of infected mosquitoes is also out of the question on the line of march. There remains, therefore, the protection to be obtained by the administration of prophylactic drugs. There is a vast amount of evidence from all parts of the world in favor of this method. There is also a certain amount of evidence showing this method to have failed. Thus it is curious that both in the Ashanti war of 1873 and in the last one, the principal medical officers did not find the practice of any value. The same occurred in the Malay war of 1875-6. In the Gambia expediton the men taking quinine had as much fever as those not taking it. But, on the other hand, there is overwhelming testimony in its favor. Time will not permit me to give all the instances in which it can be found to be beneficial to give prophylactics. What prophylactic should be used? During the latter period of his service in India he made comparative trials of fifteen different antimalarial drugs. The experiments were comparabe, as they were all made on one race of men, namely, Goorkhas, and the men were all in the same station. The result showed that quinine was *the* drug *par excellence.* Next to quinine, powdered pine bark was most successful. Narcotine, recommended by the late Sir William Roberts, was disappointing. Arsenic he found to have no antimalarial action. It has, however, been found effectual by other observers such as Crudeli and Ricchi in Italy, Downie in India, and Leslie in Africa. Sulphur and hyposulphite of soda, recommended by Dr. Schmidt, were tried in the Mauritius epidemic of 1866-7, but found to be of no use.

AMERICAN PEDIATRIC SOCIETY.

Sixteenth Annual Meeting at Detroit, Mich., May 30 and 31, and June 1.

(Continued from Page 814.)

Lobar Pneumonia Occurring in 118 Cases in Infancy.—These cases were presented by Dr. J. L. Morse, of Boston. It was his opinion that lobar pneumonia occurs more frequently in infants than is commonly supposed to be the case. In analyzing his cases he had observed that the onset was not as violent as one would generally suppose, usually beginning with fever and a cough, often with vomiting, but not frequently with a convulsion. The patient was often apathetic and drowsy. He had found that the left lower lobe was the one most often involved, next in frequency being the right upper and right lower lobes, and the entire lobe was more often involved than a part. The involved area was usually larger in the fatal cases than in those who recovered, but the part involved seemed to be about the same. 12.8 days was the average duration of fever in the cases that were uncomplicated, but had a fatal outcome; eight days was about the average of those cases who recovered. The highest temperature ranged from 103° to 106° F. Crisis was more common in the second year of life than in the first, and the temperature fell by crisis in more than half the cases. Remissions and irregularities of temperature occurred very often, but pseudocrisis was very uncommon, as was also collapse during the crisis. No patient died whose respirations were lower than 55, but the usual rate was between 55 and 80, and even when above 55 the respiratory rate seemed to have no effect upon the mortality. The rate of pulse varied from 150 to 170. In nearly one-fifth of the cases there was complicating otitis media, and empyema was a complication in about eight per cent. of the cases. The age of the patient and the amount of lung involved greatly influenced the prognosis, as the mortality was almost twice as great in the first year of life than in the second. If the temperature did not rise above 103° F., the pulse above 140 or the respiration over 55, the prognosis was good, but above these limitations it became grave, and the amount of increase seemed to have little influence on the chances of a fatal outcome.

Dr. F. S. Churchill, of Chicago, told of the case of a bay of two months who was attacked by pneumonia, the culture showing the pneumococcus and the smear the influenza bacillus. Although the infant survived the first attack, another, six weeks later, terminated fatally, but the second time the culture did not show any influenza bacilli. As the combination of these two infections is usually fatal in adult cases it was remarkable that an infant should have survived in the first instance. It was Dr. Churchill's belief that lobar pneumonia is much more common in infants than is ordinarily supposed to be the case, and that its presence is often overlooked by careless examiners.

Dr. L. E. Holt, of New York, had found the left lobe only affected in a series of 16 cases, and it was his experience that, providing the infant had been in good physical condition up to the time of the onset of the disease, the prognosis was good, if but one lobe were involved, and the pulse, temperature and respiration did not matter so much.

Dr. S. S. Adams thought the mortality rate mentioned was too high, as his private experience had been that death occurred only in about ten per cent. of cases. He advised baths only in the most extreme cases.

Dr. W. P. Northrup declared that in a few years fresh wholesome air and plenty of it would be used as a stimulant and antipyretic.

Dr. Morse stated, in closing, that he had especially wished to emphasize the fact that lobar pneumonia in infants was far more common than was ordinarily supposed, and to call attention to the fact that the rapidity of the pulse rate and respiration were not always dangerous indications.

Infant Acute Pyelitis.—Dr. R. G. Freeman, of New York, said that the acute pyelitis of infancy was sufficiently rare to pass unnoticed for a number of weeks, because the profession generally was unfamiliar with its manifestations, no account of the absence of local symptoms indicating the location of the disease. Female children appeared to be the most frequent victims, and infection from the genito-

urinary tract seemed likely, although the fact that many cases come on after intestinal disturbances, and the frequent association of the bacilli coli communis, would lead one to suspect infection from the alimentary tract. No evidence that the pelvis of the kidney was the location of the difficulty is given by the clinical manifestations. There are usually abnormal movements of the bowels, high temperature with marked remissions, sometimes accompanied by chills. Because it is a rather difficult matter to secure satisfactory urinal specimens from babies, he believed that this diagnostic method was too often neglected. Treatment was easy and harmless, consisting of neutralization of the urine. He reported the case of a male infant who gave some evidences of urethral irritation at the commencement of the attack, which had been preceded for several weeks by mild digestive disturbance. The attack lasted for three weeks, the temperature being irregular and very high toward the last, associated with nervous symptoms. Treatment was instituted on the twenty-second day of the attack, and the child made a complete recovery in eight days, remaining perfectly healthy.

Dr. J. L. Morse said he had no trouble in obtaining specimens of babies' urine for examination. In the hospital in Boston where he had gone on service the examination of the babies' urine was made a routine practice, and there were almost always some cases of acute pyelitis among the infants under treatment there, from which circumstance he judged that the frequency with which we meet this condition depends largely upon how often the urine is examined. If pus were found it was sometimes hard to tell whether it came from the kidneys or the bladder; if he saw spindle and caudate cells he referred the trouble to the kidney, if squamous cells were present it was probably in the bladder. It was, of course, a new field of investigation, but in his opinion nearly all cases were due to a colon bacillus. He had twice found tubercle bacilli in the urine, although tuberculosis was present in the kidney, and nowhere else.

Dr. Isaac A. Abt, of Chicago, reported a case of acute pyelitis where the Shiga bacillus was discovered in the urine. This would also open up a new field of investigation, as to whether this bacillus could be found in the urine.

Acute Myocardial Insufficiency in Certain Diseases of Children.—Dr. F. Forchheimer, of Cincinnati, said that a large number of acute myocardial insufficiencies developed in connection with the infections of childhood, and setting aside the possible fatal termination, there was the consideration of the lasting effects upon those children who survived. There were cases where such damage was done to the heart, as to permanently impair its function, although this condition might not be discovered until some extraordinary call was made upon it. The involvement of the myocardium was a fact now accepted by all in every case of pericarditis or encarditis, from which it could be seen how very likely acute myocardial insufficiency was to develop. The first symptoms to be noted was usually a diminution in heart force and arrhythemia, next dilatation, first of the left heart, then of the right, with insufficiency of their respective valves. Noticeable increase in the size of the liver follows the serious affection of the right heart. The author had seen cases where the liver descended to the level of the umbilicus. Weakness, tachycardia or bradycardia, irregularity of heart and pulse impulse, a broadening of the heart dulness and bruits, most commonly over the mitral and the tricuspid areas and the apex, but sometimes also over the base he regarded as the most usual symptoms. Among the acute affections he thought diphtheria most liable to cause myocardial insufficiency, generally making its appearance about the second or third week. Heart death in diphtheria is not always caused by pure myocarditis, at least two other processes may complicate it. The diphtheria toxin may affect the vasomotor centers resulting in dilation of the blood vessels, and retarding the proper propulsion of the blood, or, as it has been perfectly established that in diphtheria the vagus is often affected, this affection of the vagus may give rise to arrhythmia. Second to diphtheria, the author had experienced the septicemia of influenza, as a frequent cause of myocardial insufficiency. He had observed some cardiac changes in all the cases which had come to his attention.

Absolute rest was the first principle in the treatment of uncomplicated myocardial insufficiency. Predisposing causes must be controlled, and convalescence should be under most careful observation. If laxatives are needed those of violent action should be avoided, but strychnine and the digitalis group of drugs might be used depending on the amount of myocardium affected, while stimulants might also be indicated. In his own experience he had been able to reduce the pulse rate of one child from 140 to 60 by means of ice bags upon the abdomen to stimulate the splanchnic reflex, and saline transfusions in the beginning, to keep up the heart's contractions, with hypodermic injections of adrenal extract repeated every two hours. Except in the case of angina attacks nitroglycerin should never be employed. After the most acute symptoms had passed it was the author's custom to administer sodium salicylate and caffeine, alternating every two hours with the adrenal extract which was thus gradually withdrawn.

Dr. Jacobi stated that it was only since Engelman, of Boston, had shown the importance of the heart muscle aside from the influence of the nervous system that the necessity of studying the myocardium and its diseases had been generally recognized by physicians. It was now an acknowledged fact that a myocarditis, an endocarditis and a pericarditis might all three exist at once. Sometimes one comes in contact with an old cicatricial condition, but there are two forms of the condition, real interstitial inflammation and a parenchymatous degeneration manifesting itself under varying forms. He advised strongly against the use of digitalis as causing contraction not only of the heart, but of the arteries as well. He usually relied in such cases upon opiates such as codeine, and also made use of the iodides, and the application of ice bags.

Dr. Forchheimer stated in closing that his object had been to advocate some definite form of treatment in both chronic and acute myocarditis, and that he had endeavored to present two clinical pictures, one where myocardial insufficiency was due to a simple myocarditis and the other where it occurred as a complication.

THIRD DAY.—WEDNESDAY, JUNE 1.

Forty-Three Cases of Asthma in Infants and Children.—The analysis of 43 cases of asthma occurring in children under twelve was presented by Dr. L.

E. La Fetra, of New York. Divided according to the age of occurrence, eleven patients were under one year old, eight between one and two years, nine from two to five years, and fifteen from five to twelve years of age. The histories given were not sufficiently reliable to be of use for statistical purposes, but family history of asthma, rheumatism, tuberculosis or nervous affections was obtained in most instances. There were no Italians, and only two negroes among the patients studied, which the author regarded as peculiar, as one would naturally suppose that rickets would be an important predisposing factor, as is usual in the case of bronchitis and spasmodic croup. Rickets had been present in only eight cases, according to the history given. Two of the children had been born prematurely, 20 had had bronchitis, seven bronchopneumonia; one had had chorea, and there were two cases each of atelectasis and enlarged thymus gland. In fourteen cases bronchitis had been the cause of the attack, in two it was after pneumonia, and other cases were the result of a fall, an attack of malaria, a drive in a cold wind a gastric indigestion, etc. The periods covered by the attacks varied from "every winter" or "every summer" to those of daily occurrence. There were not three cases which were distinctly worse in summer, and in only two were the attacks more severe by day. There was emphysema associated with the asthma in ten cases, five of whom had the square or barrel chest. Nearly fifty per cent. of all the patients had adenoid growths, which the author regarded as significant. In 20 cases adenoids were associated with enlarged tonsils and one had a congenitally high arched palate without adenoids. There are few difficulties in making a diagnosis of asthma, if it is borne in mind that children are subject to it. The speedy recovery with recurrences, and the increased number of eosinophiles shown by a differential count would easily confirm it. He considered a differential count of leucocytes to be also of value. The peculiar type of breathing was induced by a narrowing of the lumen of the bronchial tubes, but there were two theories in regard to the cause of this, namely spasm of the smooth muscle fibers of the smaller and medium sized bronchial tubes, and vasomotor tumefaction or paresis, a sort of angioneurotic edema of uticaria of the bronchial mucous membrane. The proper treatment could usually be inaugurated after a careful study of the history and influences surrounding the patient. Such conditions as nasopharyngitis, bronchitis or adenoids should be considered as predisposing factors and receive careful attention. All predisposing or exciting causes should be recognized and removed. Diet and hygiene were important considerations as the general condition should be toned up as much as possible, and such measures as cold sponge bathing, open air exercise, and abundant ventilation day and night were very effective. Regarding medication, in cases of long standing or for the subacute he favored iodide of potassium. Steam impregnated with creosote he had found very useful for inhalation in the case of infants, when the attack closely resembled capillary bronchitis. If the child could swallow he gave ipecac and tartar emetic, together with nitroglycerin. He had also had success in the administration of atropine until the face flushed. If there were evidences of gastric indigestion syrup of ipecac might be used to empty the stomach, which should be done without delay. In older children he had successfully used the old mixture containing morphine sulphate, belladonna and compound spirit of ether. If the attack is due to vasomotor paresis, in accordance with this theory vasoconstrictors might be given. He had found suprarenal preparation very useful in certain instances.

Central, Peripheral and Obtrusive Dyspnea.—Dr. W. P. Northrup, of New York, mentioned three types of dyspnea; first, that of peripheral origin, neuritis, probably diphtheric and paralysis of the diaphragm; second, that of central origin, infectious transverse myelitis and paralysis of the thoracic muscles of respiration, and lastly the obstructive type, due to accidental pressure of the air in the thorax, perhaps on account of faulty exploration by the needle, not resulting from obstruction of the larynx or nasopharynx.

Dr. C. G. Jennings spoke of a very interesting case reported by him at the Boston meeting. The clinical picture was at first that of attacks of coma, but this soon changed and asthma set in. The case was one of autointoxication.

Dr. Holt was of the opinion that the only reliable remedy for asthma in a child was a change of climate. He recommended improving the general condition of such children by the use of tonics as cod-liver oil and iron, and keeping them in the open air as much as possible. Attacks of asthma were very apt to follow whooping-cough or measles.

Dr. Abt spoke of the dangers of unskilful aspiration of the chest, and Dr. Caillé said he had seen pneumothorax occur twice as the result of such explorations.

Acute Leucemia.—This was the title of a paper presented by Dr. F. S. Churchill, of Chicago. He stated that nothing could be regarded as a cause predisposing to this affection except possibly tonsilitis, and this might as well be an effect as a cause. The disease was not peculiar to children, and it ran the same course with them as with adults. Its duration was sometimes as brief as four or five days, or on the other hand it might last five months. There was invariably enlargement of the spleen, although it was not uncommon to see this organ diminish in size just before death. The blood examination was the chief point of interest. The hemoglobin and the number of erythrocytes were diminished, and the number of leucocytes ran from 6,000 to 810,000. Approaching death was denoted by a falling white count. There was a marked decrease in the number of polymorphonuclears, and almost no myelocytes. The blood tended to turn to the fatal type, but only one case in 29 presented a hemorrhage. The differential count offered the only means of making an accurate diagnosis in leucemia. A fall in leucocytes was almost always the effect of an intercurrent disease. The true nature of leucemia is unknown and all treatment was unavailing. Believing that the disease was malignant in nature some had tried the spray, but with no good result, but bacterial examination failed to give any ground for this view. He regarded any treatment as justifiable in such an obscure and fatal disease, however, and thought that serum injections seemed to offer the most hopeful indications. As twenty-nine cases had been reported he regarded it as more common than is generally supposed.

Primary Sarcoma of the Liver.—A case of adenosarcoma of the liver in an infant was reported by Dr. L. Emmett Holt of New York. The child was

poorly nourished, and on the right side of the abdomen a large tumor was palpable, filling the entire half and extending beyond the umbilicus and down into the pelvis. The tumor was smooth-surfaced, soft and distinctly outlined. Further examination was negative. There was a temperature varying between 100° F. and 102° F. A puncture of the liver was made under the supposition that an abscess might be present, and a bloody fluid withdrawn, with liver cells and fatty droplets, but no pus was obtained. The surgeon called in made an incision under cocaine anesthesia, and came upon a mass of broken down material, into which a drainage tube was inserted. The child died of exhaustion two weeks later and at autopsy the liver was found to be 19 cm. long and 21 cm. wide, weighing 735 grams. No peritonitis or thickening was noticeable. Adenoma with sarcomatous degeneration in the center was revealed under the microscope. No metatases were found, but a bronchopneumonia and a pericarditis were discovered. Only two other cases in children have been so far reported.

Radiograph of a Thoraco-Abdominophagus.—This was presented by Dr. Samuel S. Adams, of Washington, the monster having come under the observation of Dr. H. B. Sheffeld.

Election of Officers.—The following officers were elected for the ensuing year: President, Dr. Charles G. Jennings, Detroit; First Vice-President, Dr. Charles G. Kerley, New York; Second Vice-President, Dr. J. Park West, Bellaire, Ohio; Secretary, Dr. Samuel S. Adams, Washington; Treasurer, Dr. J. Park West, Bellaire, Ohio; Recorder and Auditor, Dr. L. E. La Fetra, New York.

NEW YORK STATE MEDICAL ASSOCIATION.

Twenty-first Annual Meeting, held at the Academy of Medicine, New York City, October 17, 18, 19 and 20, 1904.

THIRD DAY—WEDNESDAY, OCTOBER 19.

(Continued from Page 805.)

Twenty-five Cases of Pernicious Anemia.—Dr. Albert E. Woehnert, of Buffalo, read a paper in which he described the findings of 25 cases of pernicious anemia investigated under the care of Dr. Charles G. Stockton, of Buffalo. With regard to the microscopical findings, the blood of pernicious anemics looks much paler in color and in bad cases resembles roily water. There is a granular look as it flows, which reminds one of sand and water somewhat, and it would seem as though one were looking at individual corpuscles whose appearance is emphasized by their rarity. The viscosity of the blood is reduced and it flows more readily once it appears on the surface, while as there is a decrease of fibrin, its coagulation is delayed. The specific gravity of the blood is reduced. The hemoglobin is never reduced as much as the red cells and this sometimes gives a curiously deceitful red appearance to the blood. The most characteristic appearance is the increased size of the red cells. Poikilocytosis is noticed. Nucleated red cells occur very often and there may be curious granular appearances in the nuclear as well as the white cells. Sometimes the granules are so uniformly spherical in appearance as to resemble cocci. Sometimes they occur even in chains resembling streptococci and giving rise to the suspicion of actual microbic invasion. The tendency to take stains in various ways and so to give a varicolored picture is a very common characteristic of the blood of pernicious anemia.

Leucocytes in Pernicious Anemia.—Ordinarily the leucocytes are reduced in number. Whenever there are comparatively more white cells than red cells present, there must always be the suspicion that it is secondary anemia and not primary pernicious anemia from which the patient is suffering. In one of Dr. Woehnert's cases there was a distinct leucocytosis, however, shortly before the beginning of an intermission of the disease. As a rule, a reduction of the number of white cells is bad prognosis, while an increase in the number of leucocytes usually indicates that a period of improvement is at hand. Many of the white cells have atypical karyokinetic figures and at times two nuclei are found.

Etiology of Pernicious Anemia.—The more the picture of pernicious anemia is studied, the more is the physician forced to the conclusion that the disease is of toxic origin. There are many evidences of hemolysis. This blood destruction goes so far that the blood-making organs are not capable of meeting the demand for red blood cells, though many evidences are found in them of abnormal activity, and they endeavor to fulfil the unusual strain put upon them. The lemon-colored tint of the skin which is so characteristic of pernicious anemia and which occurs in all the cases, is due to the deposit of a certain amount of iron in the cutaneous tissues consequent upon the destruction of red blood cells and the consequent setting free of hemoglobin. There are many evidences in the internal organs of an accumulation of iron from the same cause. Whatever changes have been noted in the spleen and bone marrow, especially in the latter, are evidently secondary in character. It seems not improbable that before long the hemolytic agent, which is at work, will be discovered. Until then, the therapeutics of the disease are sure to be unsatisfactory.

Frequency of Pernicious Anemia.—Dr. James J. Walsh, of New York, said that undoubtedly many of the supposed rarer diseases occur much more frequently than was at first thought. Graves's disease, for instance, is by no means so rare as was considered to be the case twenty-five years ago. For a time statistics in this country seemed to show that diabetes was only half as frequent here as in Europe. The more careful gathering of statistics, however, has gradually brought our death-rate in the disease, especially in large cities, quite up to the standard in recent years. It seems not unlikely that many fatal cases of diabetes are still set down as nephritis or tuberculosis, these being the terminal stages of the affection. With regard to pernicious anemia, more and more cases are being discovered every year. So recently as last spring, Prof. Osler said that it was a surprise to him to find that even in good hands pernicious anemia was sometimes missed. Dr. Walsh spoke of Hunter's theory. In carious teeth a number of streptococci grew and were transferred thus to the stomach and the toxins manufactured during their growth were absorbed and proved actively hemolytic. He considered that especially streptococci were the offending agents in this microbic disturbance and suggested therefor as curative measures the most careful cleanliness of the mouth and of the gastro-intestinal tract.

Failure of Antistreptococcus Serum.—Dr. Walsh said that he had tried antistreptococcus serum very faithfully in one apparently favorable case but without success. The only result secured was a very

bothersome urticaria, which followed the injection of the serum on each occasion and for which nothing could be done. This patient had been improving when the serum was given, but the improvement did not continue and the dose was given but once a week. At the end of the sixth week she was in a very low condition and died a few weeks later. The most favorable medication in this case seemed to be the use of arsenic which on several occasions was followed by notable improvement, though it failed to be of any service at the end. There seems a general agreement now that carious teeth have nothing to do with the affection. Professor Osler announces that at Johns Hopkins the average cases of pernicious anemia have by no means unclean mouths and some of the cases have an even better condition of teeth than is normally found among hospital patients. Among the poorer classes of course the care of the mouth is by no means common, and in hospital practice it might be easy to assume that this neglect must be a common cause. It must not be forgotten, however, that pernicious anemia occurs quite often in private practice and in the better class of people who are of very cleanly habits.

Occupations in So-called Rheumatism.—Dr. James J. Walsh, of New York, said that vague pains, worse on rainy days, continued to be among the most frequent complaints treated in dispensary service and office practice. The old custom of attributing these pains to so-called muscular rheumatism, dependent upon an imaginary uric acid diathesis is gradually dying out. The number of remedies for uric acid diathesis is legion, but there is a growing suspicion that they are as little likely to do good to mankind as that other group of Scripture fame whose name was also legion. The question of the treatment of these vague pains must depend entirely upon their causation. As theory has failed in the explanation, it would seem advisable to go back to a careful examination of the patient. Dr. Walsh pointed out that many of the so-called rheumatic conditions are dependent upon various occupations and are really due to overuse of nerves when some toxic element is present in the circulation whether it be lead, alcohol, syphilis or some other foreign element.

Lead as a Factor.—In certain cases a low grade lead neuritis produces the tired feeling with discomfort on rainy days, which is sometimes mistaken for rheumatism. In one case seen, there was no other sign of lead poisoning, though the man was a painter, there was consequently considerable hesitation in attributing his condition to lead. During treatment, however, he fell and sprained his wrist and then a typical lead palsy with wrist-drop developed confirming the original diagnosis. That such things happen in diabetes neuritis is well known. It may be more or less latent for a good while, causing fatigue of muscle and vague discomfort, especially on rainy days, before the true cause and seat of the condition is discovered. Dr. Walsh pointed out that lumbago is quite frequently seen in tailors, especially those who sit in the old-fashioned position bent over their work. In them their lumbar nerves are used to maintain their position. People who lift heavy weights, especially the workers in iron foundries, bending their backs during their labor, are also prone to suffer from lumbago. Sciatica is usually more common among laborers who use their legs actively in their work. Shovelers, motormen, dentists and lathe workers are sufferers in this way. The mystery of why some people suffer and others do not still remains. It is evident, however, that some people are not built for occupations requiring the excessive use of certain groups of muscles, and if they continue to suffer from pain in them, the indication is for a change of occupation but not in the administration of the salicylates and other coal-tar products.

Rainy-Day Pains.—Whenever pains are worse on rainy days, this is at once thought to justify the diagnosis of rheumatism. It must not be forgotten, however, that affected teeth are also worse on rainy days and that a broken bone many years after union will still continue to be sensitive just before the beginning of a storm, while a dislocation usually continues to be a barometer for the rest of life. Even ordinarily healthy muscles are likely to suffer from fatigue and discomfort on much slighter provocation on rainy days. The fact of the matter is that a low barometric pressure invites blood to the surface and is sure to congest them with sluggish circulation and peripheral capillaries results. As a consequence sensitive nerves endings are pressed upon just at the time when lack of nutrition because of slow circulation makes them irritable.

Sedentary Occupations and Pains.—Painful conditions not infrequently develop in those who sit in bad positions. People who write much, not infrequently sit with one leg over the other in such a way as to cause the edge of the chair to press upon the sciatic nerve. In most people immediate discomfort is sufficient to cause any ulterior trouble. In some persons, however, there results a set of vague pains in the muscles of the leg and sometimes even in the knee.

Flatfoot and So-called Rheumatism.—Dr. Hughes, of Jamestown, N. Y., in discussing Dr. Walsh's paper, said that not a few cases of rheumatism in the feet were really flatfoot. In a certain number of cases, even where there was no giving way of the arch of the foot, the use of a support for the instep made persons much more comfortable than before. In general neurasthenia, there is often intense discomfort in the lower part of the back. In some patients this can be relieved by the use of a support for the shoulders. Dr. Hughes has seen sciatica develop as a result of awkward fatiguing positions assumed on the rifle range. These occur especially with positions on the face.

Alexander Operation.—Dr. James E. King, of Buffalo, N. Y., described a series of cases in which retroversion of the uterus was relieved by shortening of the round ligaments. The operation is available, however, not for such cases as develop pathological conditions, but as a mechanical means of holding the uterus in place. Where other pathological conditions exist besides the retroversions, the operation is likely to be a failure. Alexander's operation undoubtedly has a place, especially in young women, and as it is without danger, is almost sure to be retained in future gynecology. One unpleasant sequela of the operation is pain. This is usually unilateral and occurs most frequently on walking, though at times it is noticed even in a sitting position or as soon as the patient stands up. The cause of this seems to be some injury to the ilio-inguinal nerve, which runs close to the round ligament. The pain is most frequently seen in cases where suppuration has occurred, the nerve evidently becoming involved in the scar. Great care should be exercised not to wound this nerve, and as a rule there should be just as little manipulation of the tissues as possible. At times the operation seems to be a failure,

but this will usually be found to be due to the fact that the uterus sinks down too much, causing dragging pains. The use of a pessary, however, will usually relieve this condition. A certain number of Alexander's operations remain types of successful operation, but do not cure the patient. One unfortunate sequela is the occurrence of hernia. This is due to faultly technic in sewing up the canal or to suppuration. The canal should be sewed up just as in the operation for radical hernia. Suppuration of course must be avoided.

Passing of the Alexander's Operation.—Dr. H. O. Marcy, of Boston, said that when Alexander's operation was first introduced, he was an enthusiastic advocate of it. His success with hernia naturally made him take to it and he performed a number of the operations. Some had satisfactory and some had unsatisfactory results. In recent years he had ceased to do Alexander's operation and though it may be considered to have a place in gynecology, its usefulness is very limited and as now there is very little danger in opening the abdomen, which was one of the main reasons of the introduction of Alexander's operation in the pre-aseptic days, it now seems better to know just the condition that is present and causing the retroversion rather than attempt to correct it by an operation that so frequently failed.

Disadvantages of the Operation.—Dr. J. Hawley Burtenshaw, of New York, said that to one conversant with the anatomy of the female sexual organs, Alexander's operation ceased to have any definite purpose.

Function of the Round Ligament.—Dr. J. Riddle Goffe said that the round ligament has an important function. This is not to support the uterus, but to restore it to position when, after the emptying of a full bladder, there would be a tendency for the uterus to fall forward. It also keeps the fundus of the enlarged uterus against the abdominal wall and so avoids the discomfort that always ensues if intestines become inserted between the abdominal wall and the uterus. For retroversion of the uterus, shortening of the round ligaments will do very little. The first step if uterine retroversion is relaxation of the uterosacral ligaments. If this relaxation occurs, the uterosacral ligament must be shortened. This is not a difficult matter. They can be doubled upon each other and stitched together.

Iodine for Sepsis.—Dr. J. Hawley Burtenshaw reviewed the history of the use of iodine in the treatment of septic conditions. It was first used nearly twenty years ago by Alloway, who inserted suppositories containing from 10 to 20 grains of iodoform into the uterus in sepsis due to uterine conditions. The late Dr. Pryor put the use of iodoform in sepsis on a scientific basis and in 37 cases of puerperal sepsis had but four deaths. Of 27 cases treated without curettement by this method only one died. Of 10 cases that had been curetted before coming under Dr. Pryor's care, three died. Hence Dr. Burtenshaw has considered the advisability of introducing the introduction of iodoform into the abdominal cavity in septic conditions after operations. It had, however, proved very disappointing in practice. In Dr. Pryor's cases iodoform is absorbed so rapidly that he iodine reaction can be found in the urine in less than an hour. Dr. Burtenshaw was unable to demonstrate it either in the urine or feces and apparently it was not absorbed at all. Germs may grow on iodoform. This has sometimes been taken to mean that it is not a germicide. In the presence of animal secretions, however, iodine is set free and this proves eminently antiseptic. Dr. Burney Yeo, of London, has reported the absorption of iodoform through the skin. He uses it in the treatment of tuberculous peritonitis, employing equal parts of cod-liver oil and iodoform rubbed into the abdominal surface. He has reported a number of cures. Dr. Burtenshaw has found an extreme tolerance for iodoform on the part of septic cases. Sixty grains of iodoform may sometimes be used without the production of toxic symptoms.

The Presidential Address.—Dr. William Harvey Thornton, of Buffalo, then read the President's address, in which he insisted that the day of individual self-efficiency in medicine was past and the day of the Medical Society had come. As the result of association with members of the profession in medical societies, a marked change had taken place in recent years in the relations of physicians to one another. A sense of fraternal honor was making itself universally felt above any feeling of professional competition. Medical societies are useful not only by the information obtained by listening to papers, but by the stimulus of asociation for the physician's work and by the inspiration that is inevitably drawn from them. The members of a properly organized society are active and are continually giving off some of their energy to others, while the receptivity of members is also increased. Undoubtedly one of the most important things for professors of medical schools to insist upon with their students, is that they should join medical societies and take part with professional brethren in all movements for the benefit of the profession.

Medical Union in New York State.—Dr. Thornton said that undoubtedly the best interests for the medical profession in New York would be advanced by the union of the two at present existing organizations. Unfortunately it has been found that certain legal obstacles, which are for the present insurmountable, will prevent this union for a considerable period. In the mean time then, it behooves the members of this Association to work for the betterment of all association interests, so that when union does come, the way shall be paved for immediate prosecution of the best ends and purposes that will ameliorate professional conditions in New York. There is no reason in the world why union should not take place, and as the great body of the medical profession desires it, legal quibblers will not prevent it.

Antitoxin in Diphtheria.—Dr. Charles Gilmer Kerley, of New York, read a paper on how and when to use diphtheria antitoxin. It should be employed in large doses just as soon as the patient is found to have diphtheria. If the patient is seen on the third day of the disease, 3,000 units should be given regardless of the age of the patient. If after the third day, then 5,000 antitoxin units should be administered. This dose should be repeated in from eight to twelve hours if there has been no improvement. Improvement is considered to have taken place if there is a drop in the temperature and if there is a granular breaking down of the membrane. The dose must be repeated, however, every twelve hours, or with a little longer intervals if the symptoms do not improve. Dr. Kerley has used as high as 14,500 units and would use more if the symptoms did not abate. The doses depend not upon the age, but upon the amount of toxins present and upon the symptoms of the patient. In special forms of diphtheria as in laryngeal or nasal cases, large doses of at least 5,000 units should be employed from the

beginning and repeated every eight to twelve hours if necessary.

Intubation Cases.—Dr. Kerley considers that, in intubation cases 5,000 units should be given at once and repeated in a few hours. After 10,000 units are given, the patient should still be watched carefully, and if necessary more antitoxin given. There is no doubt now that antitoxin is perfectly harmless. It has been given in so many cases as to remove all suspicion of danger. Dr. Kerley has given it himself in hundreds of injections for curative purposes and thousands for immunization and has never seen a local abscess. In a few cases he has given it where there was no diphtheria under the suspicion of the disease, but it has produced no bad effects. It does not produce nephritis. The dose of antitoxin should not be regulated by the age of the person, but by its condition when first seen. There should be no hesitancy in giving large doses.

Success of Antitoxin.—Dr. E. D. Ferguson, of Troy, N. Y., said that antitoxin for diphtheria is the only modern medical novelty that he accepted at once. Before its introduction, he had 75 intubation cases without a single recovery. If patients did not die from the diphtheria, they died from the subsequent bronchitis, which was undoubtedly related to the diphtheria. Immediately after he began to use antitoxin, he had five successive cases of laryngeal diphtheria in which intubation was necessary without a single death. Later experiences had all tended to confirm his first impressions, and he believed most firmly that diphtheria antitoxin was a valuable remedy.

(To be Continued.)

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirtieth Annual Meeting, held at Cincinnati, Ohio, October 11, 12 and 13, 1904.

(Continued from Page 810.)

PROCEEDINGS OF SURGICAL SECTION.

The Choice and Use of Medical Literature.—This was the subject of the President's Address, delivered by Dr. Hugh T. Patrick, of Chicago. He said the daily walk of doctors differed greatly. We had the family factotum, the conversational doctor, the lodge doctor, the church doctor, the society doctor, and the doctor deep in politics. They were good friends and good citizens, but really fine physicians (?). Not one of them. And not one of them knew or cared about good medical literature. The wise, skilful physician he would like to be, read a great deal. He selects his literature well and used it wisely. The selection of books was a task as delicate, a duty as significant as was the choice of drugs. Every book was a prescription for one's mental self. Progress meant expansion. No text-book doctor was an A No. 1 man. He must have the treatise, the system, the cyclopedia and the monograph. Of all books, the monograph was the best, and the worst. It must be properly selected and read with discrimination. In medicine there was no such thing as an authority. Every paragraph was to be adjudicated. Concerning medical journals, the speaker said: "Since to advise is more human than to confess, to find fault more spontaneous than to praise, to say don't easier than to say do, I venture first to advance a few of the don'ts in my mind. Don't admit to your presence a journal that is not perfectly straight and clean. Don't indulge in yellow journals, for such there are of deeper or fainter dye. Don't take a journal which is run as an advertising medium. Don't tolerate the journal that accepts abortive papers by underdone doctors. Don't waste time on journals abounding in short cuts. Don't pay much attention to columns of formulæ, notes on treatment, therapeutic hints, brief paragraphs on recent discoveries, and items on new drugs." In conclusion, four hints were given as to the manner of reading: (1) Systematically, to get up one subject well; to investigate it thoroughly in every way. Then take up another. (2) To read up fully on cases in hand. No case can be considered alone. It is always in relation to variant cases. (3) Reading to write, providing, of course, that the writer compels himself to produce really good material. Pursuance of these three plans produces a most desirable habit—the keeping of case records. This in turn stimulates reading, and enhances its value. Accurate comparison of experience ripens knowledge into wisdom. (4) To acquire the mental habit, or attitude, or aptitude of reading for reproduction. There is a vast difference between the acquisition of knowledge as a mere accomplishment, and as a means of action. It is well for us doctors to regard our store of knowledge not simply as an interesting museum of nature's wonders, marvelous to contemplate, but rather as an armamentarium, an orderly array of goodly weapons ready for instant use.

Surgical Tuberculosis in the Abdominal Cavity, with Especial Reference to Tuberculous Peritonitis.—This was the title of an Address on Surgery, delivered by Dr. William J. Mayo, of Rochester, Minn. In St. Mary's Hospital during the ten years from October 1, 1894, to October 1, 1904, 6,408 abdominal operations were performed; of these, 183, or a little less than 3 per cent. were for tuberculous lesions. Localized in intestine, 21 times; in appendix, 29; in Fallopian tube, 44; and tuberculous peritonitis, 89. Of the latter, not over fifty per cent. remained well, although 96 per cent were discharged improved or cured, giving a high percentage of relapses within two years. About four females were operated upon to one male. In seven relapsing cases in females, reinfection was found to arise frome tuberculosis of the mucous membrane of the tube. In all, 26 cases of tuberculous peritonitis in females were subjected to radical operation for the removal of tuberculosis of Fallopian tubes. In a few females an infecting focus was found in the appendix or cecum. In a minority the source could not be traced. In men a considerable number arose from tuberculous lesion of the appendix or cecum. Tuberculous peritonitis, like septic peritonitis, was due to a local focus. A considerable number of cases of tuberculous peritonitis were cured by nature. Simple laparotomy aided recovery by permitting of more thorough encapsulation of tuberculous products and by increasing the antituberculous serums in the abdominal cavity. Removal of the localized focus of infection in the tube, appendix, etc., would greatly increase the percentage of cures and prevent reinfections. If the local focus could be removed and was primary, a general cure might be expected. If secondary to a primary disease in the lung or other part of the body, ultimate recovery depended on curability of the chief lesion.

A Plea for Wider Knowledge Concerning Diseases Which Affect the Joints.—This was the title of the Address on Medicine, by Dr. C. Travis Drennan, of Hot Springs, Ark. The author urged the necessity of greater care in every instance in which a joint was

involved, no matter how insignificant such condition might appear. The usual case of acute articular rheumatism, gout and tuberculous disease could easily be recognized under ordinary conditions, but not so much could be said when one came to the early manifestations of arthritis deformans, so-called subacute articular rheumatism, and certain forms of gonorrheal arthritis. Under existing knowledge it was well-nigh impossible in certain cases to differentiate these diseases during their earlier manifestation. When the etiology of gout was written, in his opinion it would be shown to manifest itself primarily somewhere along the digestive tract. If we could get perfect digestion, we were in a position to get perfect assimilation, and with perfect assimilation, most assuredly we were in direct line to get perfect elimination. That there was a nervous element supervening in arthritis deformans, was a view concerning which he had a well-grounded belief.

Hospital Construction in American Cities and Towns.—Dr. A. J. Ochsner, of Chicago, in a paper with this title pointed out the fact that an enormous number of new hospitals had been established, and were still being established in every part of this country; that so far the new hospitals had almost all been built by architects who based their plans on the principles which govern hospital construction thirty years ago, at which time the theories of contagion and infection were wrong. Nothing was known about differences in purity of air at different levels. The elevator had not been perfected. It was not possible to make high buildings fireproof at a reasonable cost. These changes in our knowledge being of the greatest importance should change entirely the plans of hospital construction. The importance of proper location was discussed at length. The building should be so placed as to admit sunlight to all the rooms and wards. It should be accessible to the patients and their friends and to the medical staff. This could usually be accomplished without interfering with the other important conditions. The paper then gave a number of plans for hospitals intended for various purposes, the latter being those exhibited at the Louisiana Purchase Exposition by the author, associated with Mr. M. J. Sturn, architect. Stress was laid upon the fact that millions of dollars would be spent in the construction of hospitals in the immediate future, and that it was important that the subject be thoroughly studied in the meantime.

Radical Cure of Hernia.—Dr. Hal C. Wyman, of Detroit, Mich., read a paper on this subject. The problem of hernia had been so fully worked out in the inguinal and umbilical regions, that there was nothing to do now but to find the hernial opening, and stitch it up so that the bowel would stay where it belonged in the cavity of the abdomen. In any case of intestinal hernia it was a fair presumption that the intra-abdominal space was not large enough to contain the intestines, and the abdominal walls were insufficient to embrace the abdominal contents. It was reasonable, then, to assume that surgical intervention for the cure of intestinal hernia should include measures to reduce the volume of the abdominal contents, and to increase the size and strength of the abdominal walls. Masses of omentum and part of intestines must sometimes be removed to make room; and flaps must sometimes be dragged in to supplement the insufficiency of the muscles and fascias. Suturing must be complete, absolute, and without the tension that damaged and destroyed any of the tissues. Scrotal skin and fascia might be sutured into the large hernial openings with gratifying results by making an entirely new place for impingement of the intestines that would otherwise protrude. Many patients with inguinal hernia might be permitted to get up when they felt able, with great advantage in educating the abdominal muscles to perform their offices, so that hernias did not occur.

The Typical (Anatomical) Operation for the Radical Cure of Oblique Inguinal Hernia.—Dr. Alexander Hugh Ferguson, of Chicago, contributed a paper on this subject, which was accompanied by numerous and beautiful illustrations. Dr. Ferguson described his method of operating on these cases, a full description of which may be found in the current medical literature. So far as he could determine, approximately 2,200 cases had been operated on by his method, without the recurrence of hernia.

Dr. William J. Mayo, in the discussion said, that of 600 or more operations done in accordance with the Ferguson method, only three relapses had occurred, and he was uncertain as to whether these were really due to the Ferguson or Bassini operation.

Dr. H. O. Walker considered the Ferguson method rational, and the results good. He had operated by this method over a hundred times, and had had no recurrence of hernia. He spoke of two cases in which he did a perineal prostatectomy in addition to the operation for the radical cure of hernia at one sitting, with satisfactory results in both instances.

Dr. Emil Ries favored getting patients out of bed as early as possible after abdominal or hernial operations. He did not hesitate to let his patients get out of bed on the first or second day after operation, and had had no evil results therefrom. He had used the method of Kocher in a number of cases of inguinal hernia, the main point being inversion of the sac, and had had no recurrences following this method.

Dr. A. J. Ochsner said the Ferguson operation contained the successful elements of a herniotomy. The operation should be done without traumatizing the tissues severely. He emphasized the importance of not injuring these tissues by suturing too tightly.

Foreign Bodies in the Esophagus.—Dr. Carl E. Black, of Jacksonville, Ill., reported two obscure cases of foreign bodies in the esophagus in which a positive diagnosis was made by the use of the X-ray. He made extended remarks regarding the value of the X-ray in locating foreign bodies and assisting in their removal.

Spleenless Men; Report of Two Successful Cases of Splenectomy.—Dr. J. Henry Carstens, of Detroit, Mich., stated that splenectomy was indicated in selected cases of enlarged spleen, but not in all instances. The first patient had pain and distress for a year or two in the region of the spleen, with gradual enlargement. There was sudden rapid growth within three months, filling nearly the whole abdominal cavity. Emaciation was marked. Blood examination showed destruction and irregular shape of red blood corpuscles. A probable diagnosis of malignant growth was made. Operation disclosed it to be a sarcoma. Operation was followed by complete recovery, and to-day the blood is normal. In the second case, the onset was gradual, and there was an enlargement for six months. Splenic anemia was diagnosed. The leucocytes only numbered 1,200. There was extreme debility. Operation was performed, followed by complete recovery. The

blood was now normal, and patient had gained 96 pounds in weight since leaving the hospital fifteen months ago.

Operative Work in the Ureter Through the Author's Catheterizing and Operative Cystoscopes.—Dr. Bransford Lewis, of St. Louis, Mo., in a paper with this title, considered the subject in its three relations: As a practical and reliable procedure, as a diagnostic measure, and as a therapeutic measure. After alluding to his operative cystoscope, and the instrumental equipment connected with it—ureter forceps, scissors, dilators, irrigating attachments, etc., the author considerd diagnosis and therapy. The first patient, a male, in whom the diagnosis established was that of an inactive left kidney, while the right one was not only carrying on all the kidney functionation present, but contained numerous calculi of various sizes. Ureteral manipulations through the operative cystoscope removed a dozen or more small calculi, which he exhibited, but could not secure the escape of the largest, which was removed by lumbar incision. The patient recovered, notwithstanding the fact that the only kidney functionating was opened and cleaned out. The second case related was one in which small calculi had been removed by similar means in two sittings, a year apart, the stones being exhibited. The third case was one in which there had been severe and exhausting symptoms of ureter calculus, of sixteen years' duration. There were numerous consultations, and oft repeated attacks occasionally requiring the prolonged administration of chloroform. This patient was finally and definitely relieved, and had had no recurrence of the pain for nearly a year. A case of definite and severe stricture at the lower end of the ureter had been completely relieved by dilating methods, carried out through the operative cystoscope, in successive sittings, and without complaint on the part of the patient, who was a very nervous woman. Some of the difficulties and disappointments liable to be met with in this work were alluded to and suggestions given for avoiding the most important of them.

Perineal Prostatectomy.—Dr. Joseph Rilus Eastman, of Indianapolis, Ind., said that if all prostatectomies were made as soon as the symptoms of residual urine made its appearance, the mortality would be practically *nil*. As soon as practitioners and surgeons generally realized that prostatic hypertrophy was easily curable by early operation, prostatectomy would receive the recognition which it deserved. Too often the reason for the application of the Bottini method, perineal cauterization, or other palliative procedure was that a case had been permitted to drag along with the catheter until advanced age, general sclerosis or kidney complications forbidding prostatectomy. The conservative operation of Hugh Young should be one of choice, if applicable. It consisted, as was now generally known, in making a sagittal incision closely parallel to the median raphé, through each lateral lobe, and shelling out one lateral lobe at a time, preserving the median bridge containing the ducts. After the removal of the lateral lobes, the third lobe was depressed into a lateral defect and likewise shelled out. After enucleation, Young united the separated margins of the levator ani to the end, that the gauze packing might not press upon the rectum and favor fistula formation. Clinically, the perineal operation had been proven to be the safest. In a large majority of cases prostatectomy might be completed through a perineal incision. If, however, the perineum having been opened, it was discovered that the perineal distance was so great or the median intravesical growth so large as to make the suprapubic operation necessary, such a suprapubic opening might, except in exceptional cases, be made at the same sitting. The perineal was the least bloody route, since it admitted of a complete exposure of the prostate, thereby making it easier to shell out the prostate in the essential line of cleavage. After perineal prostatectomy, the bladder *bas fond* was provided with low, level drainage instead of the up-hill or siphon drainage of the suprapubic operation. It would certainly be conceded that the danger of wounding the ejaculatory duct in any conservative operation would be lessened if the perineal operation be chosen.

Pathological Changes Resulting from Prostatic Enlargement.—Dr. Charles E. Barnett, of Fort Wayne, Ind., said there was still plenty of room in the field of research for the etiological factors in prostatic enlargement. Perverted orchidism and inflammation seemed to be the most logical causes. The former produced hyperplasia on account of a lack of orchoprostatic equilibrium. Inflammation started true adenomyoma, either or both, by stimulating the embryological matrix, on account of the infected acini, and there was a pathological evolution tumor metamorphosis from a fibro-myo-adenoma to an adeno-myo-fibroma. The pelvic fascia was responsible for all future pathology after enlargement began, on account of its ability to accommodate itself to the displacements that occurred. Anatomical study of this fascia was especially hard for the student, on account of the multiplication of synonyms found in text-books. The distorted neck of the bladder started pathology which, in its progression, finally reached the kidneys, and if it was not stopped by operative procedure upon the prostate, it would destroy them. The cases reported exemplified the vast amount of destruction done the whole genito-urinary tract from the prostatic urethra backward, and showed the fallacy of operating on patients at that stage of pathology. A plea was made for the general practitioner to discover prostatic cases early, so that the surgeon could operate on them without danger.

Dr. G. Frank Lydston, in the discussion, thought the profesion at large had accepted perineal prostatectomy as the operation of election, although there were certain cases that should not be dealt with by this route. It was the most direct route, where it was practicable to adopt it. In many instances it was imperative to treat patients palliatively until one was positive that the tumor was not only increasing in size, but was causing urinary obstruction. He pointed out the dangerous phases of prostatectomy. When the operation was done in a careful manner there was no injury to the ejaculatory ducts. There were numerous cases where sexual function had not been impaired.

Dr. F. F. Lawrence said that if surgeons could convince the general profession that hypertrophy of the prostate was a surgical disease, the mortality now attending prostatectomy would immediately decrease as it had done from operations on cases of appendicitis, ovariotomy, and other surgical affections.

Dr. H. O. Walker had operated by the suprapubic route over twenty times, and had lost one patient. At the same time, he preferred, wherever practicable, to do perineal prostatectomy. He removed a prostate suprapubically that weighed seven and a half ounces.

Plastic Surgery of the Urethra.—Dr. G. Frank Lydston, of Chicago, read an interesting and valuable paper on this subject, in which he described the methods he had found most satisfactory in his own cases.

Therapeutic Value of Radium.—Dr. Myron Metzenbaum, Cleveland, Ohio, narrated his personal observations in the clinical uses of radium. He discussed the physiological action of radium of low activities contained in hermetically sealed tubes when placed on ulcerated areas and on the unbroken skin for thirty-five minutes; also the pathological condition resulting from placing radium of high activity contained in hermetically sealed tubes on the unbroken skin for long periods of time. The therapeutic results obtained by using tubes of radium of low activity and coarse were as good in the treatment of lupus, rodent ulcer and small epithelioma as those from the use of radium of high activity and great expense. The author reported and showed photographs of three cases of lupus, and one each of rodent ulcer and epithelioma that had apparently healed by the aid of radium rays. Photographs made by the X-ray and by radium were exhibited, showing that the latter had comparatively little value in the skiagraphy of bone as compared with the X-ray. He pointed out the results obtained by suspending hermetically sealed tubes in various solutions, showing that the same had not been rendered radioactive, and therefore that hey had no special therapeutic value.

Two Cases of Pancreatic Cyst.—Dr. Van Buren Knott, of Sioux City, Iowa, pointed out the physical signs of these cysts and the difficulties which sometimes attended their diagnosis. He showed how the surgeon might be misled by the symptoms. He discussed the method of treatment, made a comparison between incision and drainage and excision, and reported two cases which presented widely different symptoms, physical signs, and morbid influence, treated by different methods. Comparison of these two cases of cysts of the pancreas had been extremely interesting to him, and revealed many striking differences. The more important of these he briefly mentioned as (1) the difference in location and anatomical relations of the tumor. (2) Neither cyst occupied the usual position for such tumors, *i.e.*, somewhat to the left of the median line. (3) Neither was a so-called false cyst of the pancreas, which had a localized collection of fluid in the lesser peritoneal cavity, but each involved the tisues of the pancreas alone. (4) The appearance in the first case of symptoms of disturbed function long before evidence of cyst formation could be detected, while such symptoms remained entirely absent in the second case, even after the tumor had attained great size. (5) The even spherical form of the pancreatic distention in one case, and the peculiar sausage-like tumor in the other, gradually expanding into a spherical termination. (6) The fact that the patient who had much the less complete operation, *i.e.*, incision and drainage, had a much smoother and more rapid recovery than the one in whom the tumor had been almost completely removed. (7) The involvement of the stomach in the first case renderd possible the wounding of its walls during the puncture of the cyst, as the true nature of the stretched, flattened and congested viscus was recognized with some difficulty. In the second case no such accident was possible. (8) The accumulation in the walls of the first cyst of a peculiar sticky, grayish, ash-like deposit, while the lining membrane of the second tumor was clean and smooth. (9) In neither case was the sallow dry skin, said to be characteristic of cysts of the pancreas, present.

Tenotomy of the Tendo-Achilles in Partial Amputations of the Foot; also in Oblique, Compound and Comminuted Fractures of the Tibia and Fibula.—Dr. J. P. Webster, Chicago, read a paper on this subject in which he drew the following conclusions: (1) It is a well-established clinical fact that after tenotomy of the tendo-Achilles (when the foot is kept at rest) the process of repair takes place and satisfactory functional use of the foot is the result. (2) It is much easier to maintain the foot in the exaggerated flexed position after the tenotomy of the tendo-Achilles than with any form of splint, anterior or posterior, metallic or plaster. (3) There is much less pain, as the foot and ankle joints are placed at absolute rest. (4) When the patient commences to walk, none of the resistance of the contracted heel cord is present, so that there is but a slight limp. (5) In oblique and comminuted fractures of the fibia there is much less danger of overriding of the fragments of bone, after a tenotomy. This greatly simplifies the care of the leg and helps to prevent deformity.

(To be Continued.)

BOOK REVIEW.

A Short Treatise on Antityphoid Inoculation. By A. E. Wright, M.D., Late Professor of Pathology, Army Medical School, Nutley; Pathologist to St. Mary's Hospital, Paddington, St. Archibald Constable & Co., Ld., Westminster.

This book consists of a series of papers, with amplifications, already published in *The Practitioner*. It represents an endeavor to forgive a "brief exposition of the scientific principles involved in antityphoid inoculation, and a summary of the practical results already achieved. Being the work of a scientist thouroughly imbued with the principles of the new German school of Ehrlich and his followers, and at the same time, conversant with the practical side of the problem, it is a timely and welcome contribution. Both of these aspects of the question, the theoretical and the practical are presented in an interesting and scholarly manner. The book is based on work in connection with antityphoid inoculation in the British Army, which included, in addition to laborious experimentation, the inoculation of 4,000 soldiers all over India, and the supply of some 40,000 doses of antityphoid vaccine during the South African war.

SUBDIVISIONS OF THE CONCRETE CONCEPT AREA OF THE HUMAN CEREBRUM.*

BY CHARLES K. MILLS.,

OF PHILADELPHIA;

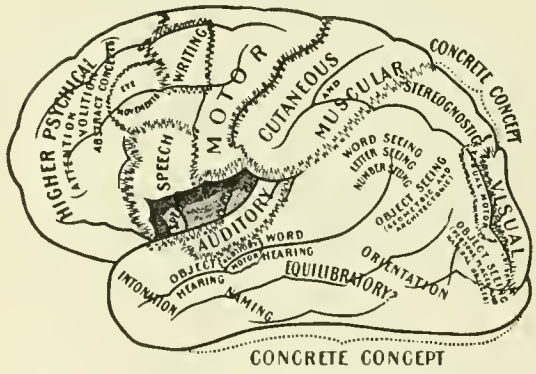
PROFESSOR OF NEUROLOGY, UNIVERSITY OF PENNSYLVANIA; NEUROLOGIST TO THE PHILADELPHIA HOSPITAL.

IN a previous paper[1] I have suggested that the term "concrete concept area" should be applied to the parietotempero-occipital region which lies between the projection areas of the cortex and largely corresponds to the great posterior association area of Flechsig. In another contribution[2] I have indicated my views as to the subdivisions of this area, which I first made to include the muscular sense, stereognostic perception, word seeing, letter seeing, number seeing, object seeing, orientation, naming, object hearing, word hearing and intonation. It is doubtful whether the muscular sense should be included in this area, and on further consideration I have decided to relegate it to the primordial regions. It belongs either here or in a position of its own between cutaneous sensibility and stereognostic perception. In the present paper I shall confine myself chiefly to a consideration of several of the sub-areas of the great concrete concept region, namely, those for object seeing and intonation, with some discussion of the cortical representation of color recognition.

Under such designations as mind blindness, soul blindness, object blindness and visual pragmetagnosia (Wyllie[3]) is described a condition in which the individual, because of a cerebral lesion or disease, is unable to recognize by sight once familiar objects. Old visual memories of the kind required for recognition of particular objects are no longer recalled. I shall not enter into any discussion of the refinements of this interesting subject, as this is foreign to my present purpose. In a note to my recent article in the *University of Pennsylvania Medical Bulletin*, May, 1904, on the physiologic areas and centers of the cerebral cortex of man, I indicated my belief that the cerebral area for object seeing was a large one and probably subdivided, especially in highly civilized man, into several subareas or centers of representation such as those for geometric and architectonic forms and for persons, places and natural objects (Fig. 1). Very few cases of object blindness with necropsy have been recorded.

In order that object blindness shall be complete and permanent, the recorded cases would seem to show that it is necessary for lesions to be present in somewhat corresponding locations in both hemicerebrums. Transient or recurring object blindness is, however, sometimes exhibited by patients with a lesion confined to one hemisphere. In twenty-five cases of otitic abscess involving the left temporal lobe, compiled by Merkens,[4] such mind blindness was present. Two cases of transient or recurring mind blindness have recently fallen under my observation. In both of these cases operation was performed for the removal of a brain lesion, presumed to be a tumor, although in one case at least the result did not confirm this opinion. In this case the patient presented in the right half of the body disorders of sensation, stereognosis and coordination. He was partially word deaf, word blind and letter blind, and late in the case showed marked hemiparesis. The operation was performed with the view of exposing the brain at the posterior extremity of the first temporal convolution. A large patch of necrotic tissue, having somewhat the shape of a pyramid with its base toward the occipital pole of the brain, was uncovered. The lesion may have extended further than was revealed by the operation. It not improbably included the caudal extremities of the first and second temporal convolutions, and possibly more.

Fig. 1.



Areas and centers of the lateral aspect of the human hemicerebrum, showing especially the subdivisions of the concrete concept area.

The operation was performed four years prior to the writing of this paper, and the patient is still living and in fair health, but is hemiplegic, partially hemianesthetic and asphasic. He suffers at times from curious attacks which can properly be described as periods of mind blindness or object blindness. The day before reading this paper I re-examined this patient. I found that his hemiplegic condition had gradually become worse, the paralysis having visibly increased, especially during the last year. He showed some slight improvement in the ability

*Read before the Philadelphia County Medical Society, May 25, 1904.

to name objects looked at, also in being able to say many words. He could not, however, form phrases or sentences. He seems still to be partially word deaf, being thrown into confusion in trying to understand much that was said to him. He continued largely word blind, but recognized an occasional word, writing being understood rather better than printed matter.

His wife who accompanied him stated that beginning about two months after the operation the patient had at irregular intervals spells of temporary mind blindness or object blindness. In these, which would last from a few minutes to one or two hours, while he would seem to know his wife, he was apparently unable to recognize others. In these attacks also he appeared unable to recognize objects or his surroundings; he seemed dazed, would look around as if wondering who the persons and what the objects around him were, repeating almost constantly one word, "What, what." He could not understand anything that was said to him at the time of these spells, and became greatly confused and irritated. His wife said that he remembered these spells after they passed off, and would say "Awful, awful," as if in great dread of them. Examination showed that he understood the use of most objects, such as the telephone, a pen, ink, shears, and paper. An effort was made to examine him for color blindness; he could not recognize red and blue, but seemed to know green and yellow; but when the examination was continued he became confused and was unable to recognize any colors.

In the second case referred to, in which operation exposing the occipital lobe was performed, and portions of the cortex removed or contused corresponding to parts of the first and second occipital convolutions, the man suffered not only from optic aphasia, but temporarily from object blindness. At first he did not at times fully recognize persons and things. The impairment was only partial.

Liepmann has recently reported a practically uncomplicated case, of mind blindness. It was first recorded clinically in 1902.[5] The patient, a music teacher, aged fifty years, had an apoplectic attack September, 1901. After this he did everything in a reverse or foolish manner, as for instance, washing in his soup. He did not recognize large objects, nor his own reflection in the mirror, but recognized persons by the voice. He did not know his own wife by sight; color perception was much disturbed. A small defect was present in the upper right quadrant of the visual field; vision was two-thirds. He could imitate large movements fairly well. Well-known objects were often wrongly named. Recognition through touch was slightly disturbed, but through hearing was normal. Motor aphasia was absent, as was also sensory aphasia, unless his wrongly naming objects might be so considered.

The patient died in 1904, two years after the case was first recorded by Liepmann. A necropsy showed most interesting results. Lesions were found on both sides of the brain, on the left in the lower occipital convolutions and on the right in the angular and second occipital convolutions.[6] at the base of the left occipital lobe was a deep cavity which indicated an area of softening, involving the fusiform and lingual convolutions. In the right hemicerebrum the area of softening was on the convexity and extended from the angular gyre through the gray and white matter of the second occipital gyre.

A case reported by Sereiux[7] is of value, notwithstanding the complication of object blindness with other symptoms like word blindness. This case, which was published in 1891, is cited by Wyllie. The patient was a woman sixty-two years old, who in 1888 had a temporary paralytic attack with lasting visual disturbances, and in 1890 had a second seizure with epileptiform spasms, hallucinations of hearing, and delirium. When examined six months later she was word blind, agraphic, word deaf, and paraphasic. She also showed marked mind blindness, with intact general intelligence. She was unable to recognize her nearest relations, said that the people around her seemed to be wearing masks, and that her daughter's face appeared as "flat as a skate." The object blindness was most marked with regard to faces, although exhibited in less degree with reference to other things. She could recognize some objects but not others; a comb, for instance, was mistaken for a pen-holder. She died of pneumonia a few months after observations of Sereiux were made. At the autopsy lesions were found in both hemispheres. In the left hemisphere were present patches of softening and in the supramarginal (subparietal) gyre, and in the caudal extremity of the first temporal gyre; on the right were large areas of softening involving the angular and supramarginal gyres, and also the caudal extremities of the first and second temporal.

So far as is known to the writer, the few other cases of mind blindness which are recorded are not of equal value with those of Liepmann and of Sereiux, but all point to the existence of centers for object recognition by sight in the tempero-occipital convolution from the second to the fourth or fifth.[8]

Studies of the brains of men noted for their powers of observation in special directions, as for instance, distinguished artists, architects, engineers, astronomers, and explorers, also of the brains of those known to have had unusual capacity in mechanical pursuits or in those callings which demand quick powers of recognition of persons and places, may eventually afford some facts of value with regard to the development of the brain in the regions in which object recognition has been localized by the above pathological findings. A comparison of such investigations with the results of the examinations of different and lower types of

brain will make these observations of especial value. E. A. Spitzka's study of the brain of Major J. W. Powell is of great importance in this direction, not only for what it teaches, but also for what it suggests as possible to future investigators. The brain of Major Powell was highly developed in the concrete concept region, and it was even possible to indicate special subareas of high development in particular portions of this region.

Spitzka in his contribution on the brain of Major Powell gives briefly the objects and history of similar examinations of the brains of notable persons.[9] The value to science of such investigations depends upon the principle that elaboration of brain structure is proportionate to the degree of intelligence. The reader interested in the subject is referred to Dr. Spitzka's paper for a most interesting historical résumé of the work done from the time of Rudolph Wagner (1860). Spitzka confines himself in his review to the question of brainweight and surface morphology of the cerebrum.

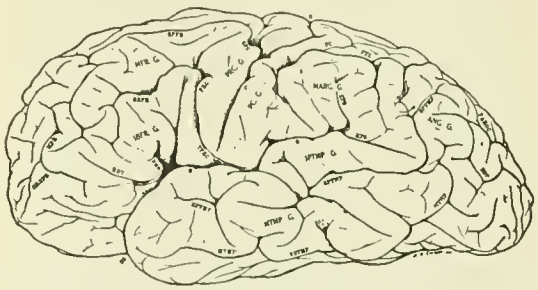
The underlying principle in the efforts to correlate the anatomy and morphology of the cerebral surface with grades of intelligence and capacity is to be found in the statement made by Spitzka that "the cortical expanse of any given area increases with the rise in functional dignity of that area." The supremacy of man over the anthropoids is expressed in the greater size and complexity of the brain of the former. Spitzka emphasizes the fact that the peculiarity of the human brain is to be found in the unusual development of the association areas and tracts—of the parietotempero-occipital concrete concept area and the prefrontal higher psychical region; he roughly estimates these areas as constituting two-thirds of the human cerebral cortex. The studies of the brains of men notable for their intellectual attainments, from Wagner's investigation of the brain of Gauss, the mathematician, in 1860, down to the recent examinations of the brains of the Seguins and of Powell by Spitzka, all indicate greater elaboration of these areas, and the finer recent work shows unusual development of particular subdivisions of these areas.

In general terms, as has already been intimated, unusual elaboration and complexity of fissures and gyres, especially in the intermediate and higher psychical areas, are the expression of unusual or at least highly specialized mentality; but this is a rule not without exception, as is illustrate by Wilder's[10] study of the brain of Chauncey Wright, with its simple fissures, broad gyres and bridged central fissures. In some higher type brains it may be that a large cortical field is obtained by broad convolutions and deep fissures and sulci rather than by the development of secondary fissures and gyres, and that in such brains the cortical layers are relatively richer in cellular elements than is the case in the more elaborated brain.

Spitzka in his paper on the brain of Powell discusses the relation of certain cortical areas to the doctrine of cerebral localization from the standpoint of the morphological and anatomical study of the cerebral surface, in particular directing attention to the correlations between special cerebral areas and the faculty of speech.

The present paper is concerned especially with the presentation of the broad features of the subdivisional localization of the concrete concept region. A large part is devoted to the demonstration of the existence of these subareas by the recital of clinicopathological cases, but in order to emphasize the importance of gyral and fissural studies, in adding to our knowledge of psychic localization, I shall presently briefly compare a few of the observations of Spitzka with some observations made and published by the writer about eighteen years ago. My studies were made on the brains of criminals, paranoiacs, idiots, and negroes, and in a single instance, jointly with the late Dr. A. J. Parker, on the brain of a Chinaman. Both before and since the publication of the papers containing these observations, I made many examinations of human brains of average and of low type, with results which have confirmed me in the views expressed in these publications as to the value, when our methods are more perfected, of such studies in adding to our knowledge of cerebral function and of many cerebral disorders, particularly those which indicate arrested or irregular psychical development. The correct method of applying morphological and anatomical studies of the human brain to cerebral localization is by a comparison of brains of the low, high, and average type with each other, and these with the brains of animals lower in the scale than man, and especially with those of the anthropoids.

Fig. 2.

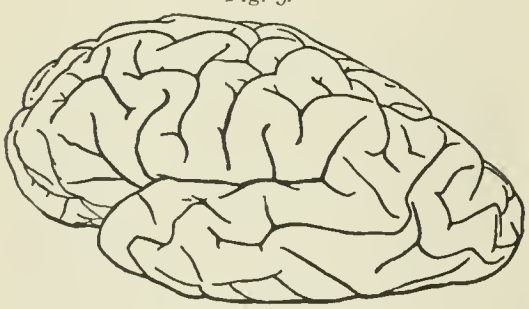


Lateral view of left hemicerebrum of J. W. Powell. This half is slightly flattened on the dorsum. One-half natural size. (E. A. Spitzka).

In Fig. 2 is presented, by permission of Dr. Spitzka, a lateral view of the left hemicerebrum of the brain of Major Powell. Both cerebral hemispheres presented a high general development, and some unusual local peculiarities; for the purposes of this paper it is best to recapitulate these in the language of Dr. Spitzka. In Major Powell's brain the most notable fea-

tures are: (*a*) "The weight of the brain, 1,488 grams, which, for a man of small frame aged sixty-eight and a half years is well above the average; (*b*) a superior degree of fissural complexity and flexuosity of the gyres not affected by the atrophy accompanying old age; (*c*) a superior degree of differentiation of the left subfrontal gyre, (*i.e.,* emissary speech center) as compared with that of the right; (*d*) the left insula (*i.e.,* associative center for the speech faculty) exhibits a slightly superior differentiation; the pre-insular pole is much more prominent than on the right, and the total size is somewhat greater; (*e*) great redundancy of the subparietal regions (*i.e.,* marginal, angular, and postparietal gyres on the right side, encroaching considerably upon the Sylvian cleft; (*f*) preponderance of right frontal lobe (mesal surface) over the left, and a proportionate reduction of the right cuneus-precuneus as compared with the left; (*g*) the precentral gyres are much wider and more massive than the postcentral; (*h*) the supertemporal fissures are interrupted at about the same site on both sides; (*i*) the epiphysis (pineal body) is unusually large." (Spitzka.)

Fig. 3.



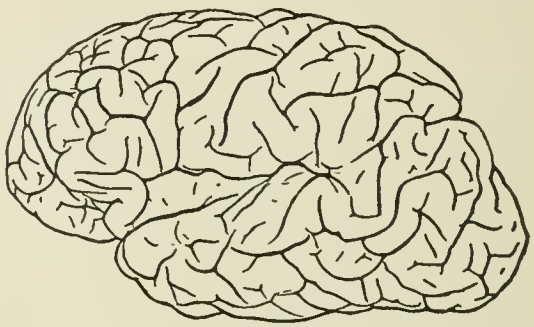
Brain of a Papuan (drawn by E. A. Spitzka from a specimen in the Anatomical Museum, Columbia University).

It will be seen that both the concrete area, including the cerebral zone of speech, and the higher physical regions of the prefrontal lobe, were especially developed. Unusual extent and elaboration of fissures and convolutions were particularly marked in some portions of the parietotempero-occipital association region, and Spitzka correlates these with well-known mental characteristics of the man as determined by opinions obtained from those who knew him best and were best fitted to judge. "The power which chiefly characterized Powell's intellectual ability was" (as would be inferred from his highly developed concrete concept region), "that of seeing analogies and making comparisons, of coupling observations and thoughts which to most people seemed not at all related to each other until by him placed in a certain light. With him the conception of the concrete outweighed thought in the purely abstract (the function, chiefly, of the frontal association areas)." (Spitzka).

A comparison of the illustration showing the left lateral aspect of Powell's brain with that of Papuan (Fig. 3) shows at a glance the extraordinary difference both in size and elaboration of the intermediate and higher psychical regions in the two specimens.[11] The brain of Helmholtz, the great physicist (Fig. 4) shows unusual elaboration both of the prefrontal and the posterior association regions.

In Figs. 5, 6 and 7 are shown photographs of three aspects of the brain of Alexander Winchell,

Fig. 4.

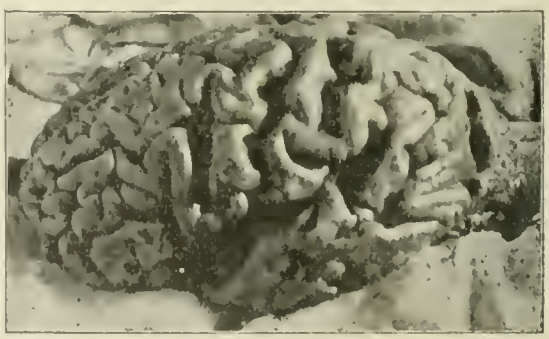


Brain of Helmholtz (after Hansemann). (E. A. Spitzka.)

LL.D., the distinguished geologist, educator and scientific author. For the opportunity of reproducing these photographs I am indebted to Wm. J. Herdman, Ph.B., M.D., Professor of Diseases of the Mind and Nervous System in the University of Michigan.

Studying and comparing the views of the lateral aspects of the left and right hemicerebrums, shown in Figs. 5 and 6, fissural and gyral

Fig. 5.



Lateral aspect of the left hemicerebrum of Professor Winchell.

complexity on both sides is evident, secondary gyres and fissures abounding. The first, second, and third frontal gyres on the right, although considerably convoluted, are well demarcated. This is not altogether the case on the left. The central fissure and the precentral and postcentral fissures and convolutions of both hemispheres are relatively simple, both the fissures and gyres are deep and wide, and the convolutions massive. The left central fissure is long and

deep, and apparently not quite confluent with the Sylvian.

Blurring of the photograph of the left hemisphere in the parietotemporal region interferes with the study of it, but some complexity is evident, especially in the supramarginal and angular region. A real study of the characteristics and peculiarities of the brain surface cannot be made from photographs, however good, and I have indicated only a few of the many interesting features which seem to be presented by the lateral and occipitoparietal aspects of the brain of Professor Winchell, which is evidently worthy of elaborte study such as has been given by Spitzka to the brain of Powell, of the Seguins, and of others.

In the illustration Fig. 7 is shown an occipital or occipitoparietal view of both hemispheres. It is of value, showing as it does at a glance, the unusual difference in the fissural and gyral arrangement and elaboration between the two hemispheres in this region. On the right the parieto-occipital region is extremely and very peculiarly

Fig. 6.

Lateral aspect of the right hemicerebrum of Professor Winchell.

convoluted. The demarcation of the typical convolutions on the left is more readily made out, the fissures and gyres here, while not of simple type, having apparently less deviations. This occipital view impresses one with the idea that the two hemispheres could hardly have belonged to the same individual.

Dr. Herdman in the letter which accompanied the photographs, says of Professor Winchell that his linguistic power was somewhat unusual; he was a good Greek, Latin and Hebrew scholar, and spoke German and French fluently; also that he was a man who was very methodical in his acquisitions, and one who could readily avail himself of the knowledge that he had acquired as occasion demanded.[12]

From his boyhood Professor Winchell was a close student, both of nature and of books; he was skilful in the use of his eyes and hands, being a good offhand draughtsman and manipulator of geological tools and scientific instruments; he was a prolific writer, particularly on geological subjects, his writings showing him to be not only an excellent observer and investigator, but also one possessed of a scientific imagination and reasoning powers of a high order.

In the *Journal of Nervous and Mental Disease* for September-October, 1886, and in *The Philadelphia Polyclinic* for September, 1886, the writer described the peculiarities of the fissural and gyral development in the brains of several criminal paranoiacs, giving photographic illustrations of different aspects of the brains in these cases. A valuable lesson is to be learned by comparing these illustrations with the projection drawings of Spitzka in the left hemispheres of the brain of Major Powell and of the Papuan, and with Hansemann's illustration showing the same side of the brain of Helmholtz. Striking differences are readily made out between the anterior and posterior association areas of the high and the low type brains respectively. Writing in 1886, I summarized as follows the most important indications of inferior development shown in one of the brains described as the comparatively simple type

Fig. 7.

Occipitoparietal view of the brain of Professor Winchell.

of the frontal lobes, the partial exposure of the insula, the confluence of the right central with the Sylvian fissure; the confluence, almost complete, of the right and less perfect on the left of the calcarine with the hippocampal fissures, the ape-like similarities shown by the annectant gyres on both sides, the shallowness, shortness and complete bridging of the right calcarine fissure, the imperfect angular gyre of one side, and the simplicity of the tempero-occipital and parieto-occipital regions.

Writing years before the observations of Flechsig, of Wilder and of Spitzka were published, it is interesting to note what is said about the simplicity and the aberrancy of the tempero-occipital and parieto-occipital regions in another low type brain. Many ape-like peculiarities were shown in the gyres and fissures generally, these being especially marked in the parietotempero-occipital region. The markings of the frontal lobes of both hemispheres in this

brain were simple; the intraparietal fissure was unusually long and only partially bridged; the supramarginal (subparietal) gyre was small; the superior and inferior annectant gyres were somewhat aberrant. Wernicke's fissure (the homologue of the external perpendicular fissure of the ape) was clearly outlined, communicating with the supertemporal fissure, and other interesting peculiarities indicating low psychical development were present.

Some of the conclusions reached in the papers above cited, both from a general study of the subject and the investigation of the low type brains, with regard to the peculiarities which probably indicate a low or aberrant order of human brain, are of interest in connection with our localization studies of the high and intermediate psychical areas, and also have especial interest by contrast in reviewing the work done by Spitzka and others on the brains of those high in the intellectual scale. The subject is fairly well covered in the following citation: "In general, simplicity of structure, with well-defined and comparatively little-complicated fissures and gyres, point to a low type; simplicity of the frontal fissures and gyres in particular indicates an inferior order of brain. Unusual symmetry and atypical asymmetry are indicative of a low type. Normal human brains present atypical asymmetry."

Coming to special details, Benedikt refers to a fissure, which he terms the external orbital, very constant in apes, and not commonly distinct in the human brain, but rarely absent in criminals' brains examined by him. Partial or complete uncovering of the insula, that is, its exposure to sight without pulling apart the margins of the Sylvian fissure, is to be expected in white brains of inferior grade. The Sylvian fissure in the average brain is of moderate length; the higher the type, other things being equal, the more likely it is to be short. The central fissure in inferior types will be less sinuous, and less likely to be fully separated above from the sagittal or longitudinal fissure and below from the Sylvian. In poorly developed hemispheres the gyres bounding the central fissure will not be sinuous and complicated—that is, will present little elaboration. An unusually well-defined, elongated, or unbridged parietal fissure; a small marginal gyre, as when the parietal fissure approaches closely to the Sylvian; a much elongated so-called retrocentral (postcentral of Wilder) fissure; and an occipital fissure which opens well out on the lateral surface, with the superior *pli de passage* below the brain level, are probably indications of inferiority.

Shortness of the Sylvian fissure, in more highly evolved brains, tends to confer a corresponding shortness in the temporal lobe; the opposite is seen in brains but little evolved. Other peculiar conditions of the temporal lobe seem to be indicative of low type; as great length, particularly of the posterior vertical arm of the supertemporal or parallel fissure, with a tendency to confluence with the Sylvian, occipital, or parietal fissure. Such a tendency indicates a lack of development of Gratiolet's transition gyres of the tempero-occipital and parieto-occipital regions. On the median surface of the hemisphere, some indications of inferiority are smallness of the paracentral lobule and precuneus, confluence complete or incomplete of the calcarine and hippocampal fissure, and unusual definition of the median portion of the occipital fissure, although curiously, in a few brains of low type an unusual development of the so-called gyre of the cuneus, or inferior internal *pli de passage*, is observed. This is an aberrant or peculiar condition, certainly not usual in the average human brain."

The question of the existence of separate cerebral centers for color, luminosity and form is one which deserves consideration in connection with the particular subject of the present paper. If special centers for color exist, they are probably just within or just outside of the primary visual areas for light, in other words, within or on the borders of the cuneus and the first occipital convolution. A few facts of physiology and of clinical medicine seem clearly to indicate the existence of such centers. A few cases of unilateral congenital color blindness have been put on record. In some of these red and green have been confused as in the more usual cases of bilateral color blindness. In other instances the unilateral color blindness has been total. The unilaterality of the symptom is in itself suggestive of the special localization for color representation.

Occasionally color blindness is associated with hemianopsia, or with quadrant or sector defect, in other cases, more interesting in connection with the subject of color representation, hemiachromatopsia is present without hemianopsia.

Two of the most interesting cases of achromatic defect with lesions of the brain demonstrated by necropsy are those of Brill and of Verrey. As the case of Brill, although reported twenty-two years since, has received little or no attention from writers on the subject, and as it is a case of unusual interest, I shall refer to it in some detail.

The patient, a man sixty-three years old in October, 1881, had an apoplectic attack resulting in right hemiparesis, right hemianesthesia, incontinence of urine, and increased right knee-jerk. After several weeks these symptoms were changed and supplemented; the anesthesia of the thigh became hypesthesia, tremor of the paralyzed side developed, and the patient suffered from headache, restlessness and insomnia, with occasional spells of tinnitus aurium and dazing, and also dulness of mind. His sight became dull and hazy. Four months after the attack the patient was examined by Dr. Brill and Dr. E. C. Spitzka in consultation. He failed to recognize green; he was doubtful as to whether violet was greenish or bluish; green he said was red or

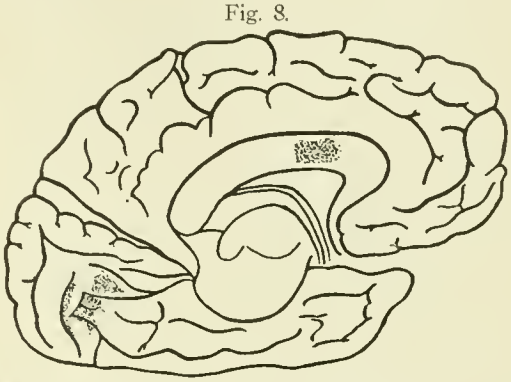
rather pinkish; he could always recognize red and yellow. The color loss involved both eyes. Gross objective vision was retained except a subjective blurring; the fields of vision were not limited. The patient was illiterate so that his condition as to letter and word blindness could not be determined. He had worked on the railroad for thirty years before his illness, and was able to recognize all colors.

He died about 6½ months after admission to the hospital. At the necropsy a softened area was found at the apex of the left cuneus and the adjoining upper part of the lingual convolution. Brill exactly describes the area of softening as follows: "The focus was triangular, the apex being directed forward and the short side posteriorly. It extended to within a centimeter and a half of the apex of the occipital lobe, and involved half the altitude of the cuneus in the middle of the latter, and almost the entire apex of this lobe. The gyrus lingualis was involved for about one-quarter of its width on the surface, and evenly from the posterior almost to the anterior extent of the lesion described. The calcarine fissure could not be identified excepting its most anterior extremity, and even at this spot both borders were softened.[13] At its lowest border the softening reached almost to the posterior cornu. Brill cites chiefly from Exner's work[14] on cerebral localization, cases of Exner, Vaultier, Fürstner, Reinhard, Quaglino, Boys de Lory and Förster.

Verrey reported sixteen years ago the most interesting case of hemiachromatopsia with necropsy, showing the lesion to which the loss of the chromatic sense was due, which has yet been put on record.[15] The patient was a woman sixty years old, whose symptoms were difficulty in reading, with good general visual acuity, slight concentric contraction of the field, complete absolute right hemiachromatopsia, and a sensible diminution of visual acuity for the right half of the visual field. The patient had paroxysmal headache and attacks of vertigo with vomiting. She gradually developed fatigue in reading, with letter dancing and dyslexia. Examination showed that with her central field she could read letters and words written in different colors. Twenty days before her death the patient's symptoms were much the same as above summarized, with the exception of a further enfeeblement of luminous perception. Eight days before her death she fell, and at this time developed a complete left hemiplegia, entire cutaneous irresponse, violent vomiting and clonic and tonic convulsions of the face and right side. The necropsy showed recent large hemorrhage in the right hemisphere destroying the centrum ovale and the basal ganglia, and filling the right lateral ventricle. A fresh hemorrhage the size of a bean was situated at about the junction of the anterior and middle third of the left callosum. A second lesion was found between the floor of the posterior horn of the left lateral ventricle and the basal surface of the occipital lobe. Close examination showed a large thrombosed vessel, and that the parts destroyed were the white substance of the third occipital convolution, more or less completely the white substance of the occipital extremities of the lingual and fusiform convolutions, and the posterior inferior point of the cuneus (Fig. 8).

According to Verrey, up to the time of the publication of his paper, eight cases of hemiachromatopsia had been reported. Some of these were associated with verbal blindness, alexia, dyslexia, or other visual disturbances of language, but in some the hemiachromatopsia was not thus accompanied, and Verrey therefore concludes that hemiachromatopsia of cerebral origin, having its seat in the left hemisphere, may exist without being accompanied by verbal blindness. The same has been proved by others to be true of hemianopsia. The cases both of Brill and of Verrey prove that a center for color recognition, and for the chromatic sense is on the

Fig. 8.



Mesal aspect of the left hemicerebrum showing the cortical extent of a lesion causing hemiachromatopsia, in a case recorded by Verrey; the subcortical radiations of the lesion are described in the text. A small lesion of the callosum is also shown.

mesotentorial surface of the hemicerebrum, probably in the fusiform and lingual convolutions. Not improbably also in part the sense is located in the adjoining portion of the cuneus. In Brill's case it would seem from the report that the condition was not a hemiachromatopsia, but one of bilateral partial color blindness, although unfortunately the writer is not sufficiently explicit with regard to this point.

The chromatic half retinal representation would be most likely to be situated on the mesotentorial surface of the hemisphere. Verrey makes the valuable suggestion, which was partially demonstrated by the study of his case, that somewhat higher on the mesal surface of the occipital lobe than the area for the chromatic sense, is located in successive order the representation of form and of luminosity.

It is highly probable that just as we have a lower or primary visual cortical area in the cuneus and first occipital gyre, and a more highly evolved area in the angular region, the former representing retinal half fields and the latter the

central or macular region, so color recognition has two distinct cortical areas of centers of representation, one mesotentorial for the chromatic half fields and the other lateral occipital in the neighborhood of the angular gyre for color recognition by the macula.[16]

The cerebral representation of the musical sense, or of what some prefer to call intonation, or even note hearing, is one which has engaged the attention of a few of the best known workers in the field of localization, as well as of others who have turned to the subject because of its esthetic side. For reasons which will presently appear, intonation has an area of cortical representation entirely separated from that for word hearing, although doubtless not far removed from the latter. In the diagrammatic scheme (Fig. 1) it has been placed in the cephalic extremities of the first and second temporal gyres where its location is indicated by anatomical, morphological and clinicopathological investigations.[17] I shall confine myself to a presentation of a few of the most important facts indicating the separate localization of this so-called musical sense.

The localization of a musical center or, speaking more correctly, of a center for the appreciation of the relation of tones, early engaged the attention of Gall and his school. Gall indeed devoted much time and work to the establishment of this localization, the result being that he placed this center over the Sylvian fissure, in the upper and lateral part of the forehead, in the temporal region almost bordering on the supraorbital ridge. As the parts of the brain corresponding to this cranial localization would be in large part the anterior extremity of the temporal lobe, Gall's localization in this case, as in that of speech and of higher reasoning faculties, was probably nearly correct. Others have located the intonation area elsewhere, Flechsig, for instance, in the subparietal region.

A few facts well known to students of cerebral disease, and especially of aphasia, clearly indicate the differentiation of word hearing and the musical sense. Aphasic patients, the aphasia in some cases being almost total, may retain the musical faculty. A number of such cases have been recorded. A few cases with note deafness without word deafness have also been recorded, one by Grant Allen,[18] for instance, the case being that of a young man who was entirely unable to recognize musical notes, and yet had no affection of hearing or speech.

Occasionally the musical defect, evidently due to localized cerebral disease, has reference only to high tones.

In somewhat numerous cases word deafness and note deafness or musical deafness have been associated in the same case, and in a few of these one of the defects has been recovered from while the other remained. In a case recently under the observation of the writer, a man, forty-four years old, after an apoplectic attack, became word deaf, word blind, and paraphasic. During the first four or five weeks after the cerebral seizure causing his aphasia, from the statements of both his wife and daughter, the patient seemed to have entirely lost the power of appreciating tones of music. Although his aphasia was still of a most serious character when seen by me, a little more than three months after his attack, he had largely regained his power of appreciating music. On testing him by having his daughter play on a piano, he was able to hum tunes which had been well known to him, in unison with the instrument, although he could not recall the words of the songs, or even their names. A case like this indicates that while the center for tones is separate from that for words, the two are in the same general region of the cortex, and a destructive lesion involving one probably implicates the other by pressure or temporarily by edema.

As bearing upon the subject of music or tone representation in the cortex, the well-known fact may be recalled here that a considerable number of cases of mental enfeeblement, or even of acknowledged idiocy are able to repeat tunes or appreciate music, although deprived of the faculty of speech. In comparatively rare cases the insane retain the musical faculty after the mind is largely disintegrated and the speech faculty has for the most part disappeared.

One of Spitzka's conclusions regarding the brain of Major Powell is interesting in this connection. "The rather superior, but not extraordinary, development of the area in closest proximity to the auditory field," says this writer, "can safely be correlated with his good appreciation of music, not only of European composition but of Indian as well, as shown in his masterly analysis of Indian songs and melodies. As Dr. McGee has stated, Major Powell was a 'potential musician,' if not a trained one, and this statement is supported collaterally by the fact that his daughter and other blood relations are highly accomplished musicians.[19]

In the few well observed and well recorded cases of amusia in which necropsies have been obtained, the lesions have involved the anterior portion of the temporal lobe, usually the first or the first and second temporal gyres, although sometimes in addition some of the cortical matter hidden within the Sylvian fossa.

8 At the recent meeting of the American Ophthalmological Society, held in Atlantic City, July 13 and 14, 1904, Dr. W. A. Holden, of New York, presented a report of a most interesting "Case of Mind Blindness, Unique in That the Entire Mesial Surface of Both Occipital Lobes and Both Optic Radiations Were Preserved." Through the courtesy of Dr. Holden I am able to make brief reference to this case, which will be published in the Transactions of the Ophthalmological Society. This patient, after two apoplectic seizures—the first eight years and the second seventeen months before his death—became emotional, depressed, mentally confused, aphasic, hemiparetic and mind blind. He also developed delusions of marital infidelity, visual hallucinations, and failed in memory, gradually growing weaker physically and mentally until his death. Necrosy showed

that the parietotemporal branch of the medicerebral artery in the Sylvian fossa was occluded on each side. This occlusion caused on the left necrotic softening of the posterior part of the left temporal lobe of the lower and posterior part of the supramarginal (subparietal) gyre, of the whole of the angular gyre and its adjacent parietal borders. A sunken, older-looking lesion was present near the occipital tip. On the right the softening involved the whole of the supramarginal (subparietal) gyre, the upper portions of the angular and postparietal gyres, the lesion reaching back into the occipital lobe just behind the parieto-occipital fissure, nearly to the mesal edge of the hemisphere. The upper half of the postcentral convolution was also damaged. It will be seen that the report of this case, taken in conjunction with Liepmann's case, and other cases, confirms the writer's view of the large parietotempero-occipital area concerned with object seeing in its different forms.

9 Dr. Spitzka's paper was read in part before the Anthropological Society of Washington, and was published in full in the American Anthropologist (N. S., V. 5, No. 4, October-December, 1903). The writer is indebted both to Dr. Spitzka and to the editors and publishers of the Anthropologist for the privilege of using the illustrations, figures 2, 3, 4.

10 Journal of Nervous and Mental Disease, 1896, p. 706.

11 The brain of the Papuan was drawn by Dr. Spitzka from a specimen in the Anatomical Museum, Columbia University, and is used by his permission, as is also the brain of Helmholtz (after Hansemann), shown in Fig. 4. These illustrations, like that of the brain of Major Powell, are taken from Dr. Spitzka's paper, already referred to, in the American Anthropologist.

12 On May 3, 1891, Professor Mark W. Harrington read a memorial address on Professor Winchell before the University of Michigan. This address has been published in pamphlet form, and from it a good idea of the habits, acquirements and mental characteristics of Professor Winchell can be obtained.

13 American Journal of Neurology and Psychiatry, V. 1, N. Y., 1882. Previous to the report of the necropsy, Brill had reported this case clinically in the Chicago Medical Review, April 1882.

15 Verrey, Arch. d'Ophthal., Par., V. 8, July and August, 1888.

16 For a fuller discussion of this subject in its different bearings the monographs and works of Verrey, Munk, Wilbrand, Swanzy and Norris and Oliver should be consulted. Mackay, at the annual meeting of the Section of Ophthalmology of the British Medical Association, held at Glasgow, August, 1888, presented an interesting contribution specially discussing acquired color blindness and the question of the separate recognition of color, form and light, giving a table of cases up to that date (British Medical Journal, Nov. 10, 1888).

17 In the recent series of papers on cerebral localization by the writer, of which this is one, this subject might have been appropriately considered with that of aphasia and the cerebral zone of speech (American Journal of the Medical Sciences, September, 1904), but for reasons of convenience it is discussed here. It is not, however, out of place in this connection, as the area for the musical sense, like that for other forms of symbolization, may in part at least be considered as belonging to the great concrete sphere of the cortex.

REPORT OF A CASE OF SPLENOMEDULLARY LEUCEMIA TREATED FOR NINE MONTHS BY THE X-RAY.[1]

BY WILLIAM FITCH CHENEY, M.D.,

OF SAN FRANCISCO, CAL.;

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, COOPER MEDICAL COLLEGE, AND PHYSICIAN TO LANE HOSPITAL, SAN FRANCISCO, CAL.

W. A., whose case is here reported, first came to my office August 4, 1903. His age at that date was twenty-seven years. He is a native of California, has always resided in this state, the past eight years in San Francisco. His family history is excellent, for his father, mother, two brothers and two sisters are all living and well, and no brothers or sisters have died. He was always well previous to his present trouble, except for several attacks of tonsillitis—he recalls three or four such attacks in all. He never had malaria. He came to San Francisco in 1896 to work as a bookkeeper, and continued at that occupation until compelled by his present illness to give it up. The history of this present illness naturally divides itself into two periods and will be so described for the sake of contrast. The first period is that from the time the symptoms were first observed until X-ray treatment was begun; the second period covers the last nine months, during which X-ray treatment has been given.

First Period—April, 1902, to October, 1903.—In April, 1902, the patient first noticed that he was pale, weak and short of breath on walking. He then consulted Dr. J. H. Graves, of this city, who found the spleen enlarged, the blood count and smears characteristic of splenomedullary leucemia, and gave Fowler's solution for a month without effecting any material improvement. The patient was then persuaded by friends to consult a homeopath in this city in June, 1902, who never examined his blood at all, but diagnosed malaria, and treated him for eight weeks for that disease. Growing no better, the patient then gave up his work and returned to his parents' home in Monterey County on September 1, 1902. In September, beginning about the tenth, he had an attack characterized by severe pain in his left side, which kept him in bed for ten days—the first and only pain he has ever had during his illness. He remained at home until December 1, 1902, then returned to San Francisco and went to work again for his old firm, but traveling about "drumming" trade instead of keeping books in the office. This work he continued for three months; but all the while he felt very weak and tired, and his abdomen was steadily enlarging.

The latter part of February, 1903, he once more gave up his work and went to Byron Springs in search of health. There his blood was again examined by Dr. Robert Crees, who once more found the condition to be a splenomedullary leucemia. Remaining in Byron Springs only one week, the patient returned to San Francisco, and to Dr. Graves, who had first diagnosed his case; but after only a brief stay here he went on to his home in the country. There he remained until the following August, taking quinine, arsenic, and iron at intervals for four months; but continuing weak, pale, unable to work, and with abdomen constantly enlarging. On June 30 and July 1, 1903, he had a severe attack of epistaxis, and lost considerable blood, but there was no other unusual incident in his history during the months he remained at home.

When first he came to me, on August 4, 1903, he was very pale, dyspneic and weak. His abdomen was greatly distended, tense, and caused much discomfort; and in addition to the splenic tumor it contained a small amount of ascitic fluid. His digestion was much disturbed and sleep interfered with by the intra-abdominal pressure. There was no pain or tenderness over the long bones. No organic disease could be made out in the lungs or heart, and the urine was normal. Nowhere were there found enlarged lymphatic glands. The liver was not enlarged. The spleen on August 6 reached 12 cm. below the level of the umbilicus, 5 cm. to the right of the median

1 Read before the California Academy of Medicine, June 28, 1904.

line, and its total vertical area of dulness measured 39 cm. Of the first blood examination, made by Dr. Graves in April, 1902, I have not been able to obtain any report. Of the examination made on February 27, 1903, Dr. Crees gave the following report: Reds, 2,560,000; whites, 495,000; hemoglobin 60 per cent. No differential count was made at that date, but Dr. Cree's report states that myelocytes were seen in large numbers and nucleated reds were found. A later count, made by Dr. Crees on March 5, showed 371,000 white corpuscles. A differential count made by Dr. Graves on March 10, 1903, showed the following: Myelocytes 43 per cent; polymorphonuclears 37 per cent.; large lymphocytes 8 per cent; small lymphocytes 7 per cent; eosinophiles 5 per cent; and occasional nucleated reds were noted.

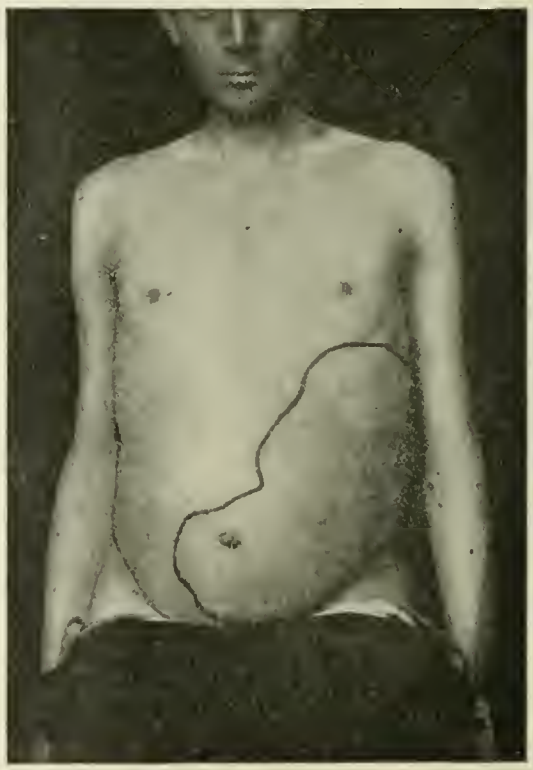
On his second visit to my office, on August 6, the white count was 220,000, but at that date no differential count was made. He was then put upon routine treatment: Fowler's solution in ascending doses, which were well tolerated; but during the month of August, while on this treatment, his condition grew rather worse. On September 2, after one month of arsenic, his blood examination gave the following: Whites, 141,000; reds, 1,620,000; hemoglobin 37 per cent.; myelocytes 45 per cent.; polymorphonuclears 25 per cent.; large lymphocytes 15 per cent.; small lymphocytes 7 per cent.; eosinophiles 8 per cent.; nucleated reds, 40, while counting 295 whites. Because his condition was at least no better and because no definite promise of improvement could be made him, the patient concluded to return to his home in the country, and did so early in September.

Thus, at the end of the first period of the illness, in spite of the employment of all the ordinary and well tried methods of treatment for this ailment, by several different physicians, this man's condition was distinctly worse than at the outset, and the outlook was for a fatal termination of his illness within a few months at most. He was practically sent home to die.

During the month of September, however, my attention was attracted to the article by Senn, published in the *Medical Record* of August 22, 1903, describing a case of splenomedullary leucemia treated by the X-ray with apparently great improvement. This plan of treatment had at least the virtue of novelty and seemed worthy of trial. I therefore wrote to the patient, advising him to return to San Francisco and make the experiment, at the same time explaining the uncertainty that any good would result. He decided to try the X-ray as advised, and returned to San Francisco September 29 for that purpose.

Second Period—October 1, 1903, to July 1, 1904. Condition at Outset of Treatment.—Before treatment with the X-ray was begun, certain data were collected as a basis for determining results: (1) *General condition:* It was recognized that a change in the feelings of the patient must be looked upon as unreliable evidence of improvement, unless accompanied by other more tangible proof; and yet his discomforts were so obvious that any disappearance of them could be noted by the observer, as well as by the patient himself. The marked symptoms of illness were the pallor, weakness, shortness of breath and abdominal distention; about the presence and degree of these there could be no question. They had been present for a year and a half, gradually grown more pronounced, and had kept the patient from doing any work for the previous six months. No treatment employed had ever done more than temporarily mitigate these symptoms, and nothing had ever removed them, even temporarily. (2) *Condition of the Abdomen:* The abdomen, on account of the greatly enlarged spleen, was exceedingly tense. The spleen was quite immovable on change of the patient's position. There was a moderate amount of ascites present. The outline of the spleen, as determined by palpation and percussion, was marked out on the surface of the body, and a photograph taken on September 30, 1903, which is herewith presented. The measurements, as set down on September 30, were as follows: Circumference of the abdomen at the navel, 95 cm.; tumor extends 12 cm. below level of navel, 5 cm. to right of median line below level of navel, but not to right

Fig. 1.



Photograph of patient, W. A., taken September 30, 1903; showing outline of splenic tumor.

above level of navel; total vertical dimension of dulness 39 cm. Patient's weight at this date 175 pounds. (3) *Condition of the Blood:* This examination was made for me by Dr. H. R. Oliver, instructor in pathology in Cooper Medical College. It showed on October 1 the following count: Red corpuscles, 2,508,000; white corpuscles, 126,000; hemoglobin, 47 per cent.

With these data obtained, X-ray treatment was begun on October 1, 1903. Arsenic and all other drugs were then discontinued, and none have been given since the X-ray was begun. The applications were all made for me at Lane Hospital by the internes there—Dr. George Coleman, Dr. Charles Coleman and Dr. Garth Parker.

Mode of Application.—Throughout the course of treatment the static machine and the street current were used, one about as often as the other; and a "soft" or low vacuum tube made by Queen. The duration of treatment was usually twelve to fifteen minutes. The tube was almost invariably held at a distance of ten inches from the body, but in a few instances as close as eight inches. The site of exposure was the splenic tumor as a rule, either directly in front or on the left side. Whenever there was any skin reaction, even the slightest, the splenic area was let alone for the time being and the applications made over the long bones—thighs and legs especially and the sternum less frequently. At first the exposures were made once each day; but it was soon found that the skin would not tolerate this frequency, and therefore the plan was adopted of giving them every other day. Once or twice treatment had to be interrupted altogether for a week or more because of dermatitis. During the nine months, October 1, 1903, to date, the patient received in all 144 applications.

Effects of Treatment.—Reviewing these in the same order as the data considered at the outset, I will speak of (1) the *Effects on the General Condition:* This promptly showed improvement. At the end of the first week of daily treatment, the patient reported that he felt much better, did not tire so easily, could walk further, and could eat without abdominal distress. From October 11 to November 7 treatment had to be interrupted part of the time because the X-ray apparatus was out of order, but mainly because of an extensive burn at the site of application. But it was resumed November 7, and though treatments were never daily thereafter, the patient by the end of November reported that he felt perfectly well; he had lost his pallor, looked well, had gained ten pounds in weight, and felt none of his old symptoms of weakness, dyspnea, and abdominal distress. From that date on to the present time his invariable report has been that he feels perfectly well and would not know anything was the matter with him except for his enlarged abdomen and his blood counts. He went back to his old occupation on December 1, 1903, and has worked every day continuously since that date. It is absolutely certain that his health is better now and has been better since November, 1903, than it had ever been at any time during the previous year and a half he was under treatment, before beginning with the X-ray; and it may be asserted with equal positiveness that from a symptomatic standpoint the man is cured.

But the other manifestations of disease have not kept pace with the symptoms. As regards (2) *the Effects on the Condition of the Abdomen*, improvement has certainly occurred, but restoration to the normal has by no means been accomplished. Change here has been very slow, and is even yet more subjective than objective. The first effect noted was the disappearance of free fluid from the abdomen, which was no longer demonstrable after the end of November. Gradually also the spleen has become more freely movable within the abdomen; and the tension has undoubtedly decreased, so that the wall has become less resistant to palpation. But the measurements, made regularly once a month, have shown very little change from those found

Fig. 2.

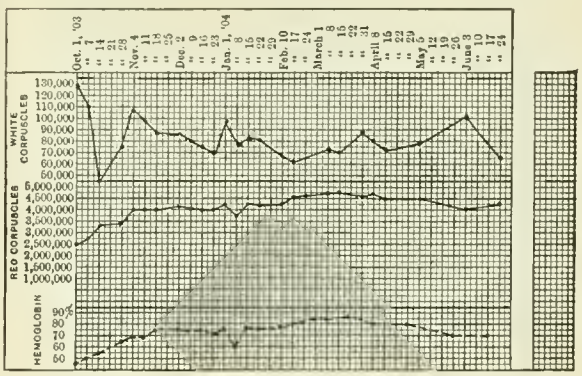


Chart showing condition of the blood during the nine months patient was treated by X-ray; the straight black line at the top indicates continuous treatment, while the breaks indicate interruption of treatment.

at the outset of treatment. The circumference at the navel has never been less than 94 cm.; the distance of the tumor's extent to the right of the median line has never been less than 3½ cm.; and the distance below the navel never less than 7 cm.—this latter dimension being the only one that has shown any decided decrease. At the present writing it must be admitted that, while the patient's general appearance and nutrition is improved, the contour of his splenic tumor has not materially changed. (3) *Effect on the Condition of the Blood.*—For my knowledge of this I wish to thank Dr. Oliver, who has made regular examinations all during the time of treatment. His findings are given in the accompanying blood chart. The effects of treatment on the blood will be best considered by taking up the various elements separately. *A. The White Count.*—Here the least effect has been produced. The chart

shows that while at the outset the white corpuscles numbered 126,000 and have once fallen as low as 45,000, they have never approached more nearly than that to the normal, and most of the time have fluctuated in number between 70,000 and 90,000. There is apparently a definite relation between the frequency of the X-ray applications and the decrease in the white corpuscles. During the initial period of treatment, when it was given every day the whites rapidly tumbled from 126,000 to 45,000 in two weeks. Then as treatment had to be discontinued because of dermatitis, the whites steadily rose again to 110,000. When treatment was resumed they once more gradually fell to 70,000. Similar fluctuations have so repeatedly been observed, apparently dependent upon the regularity or irregularity of treatment that it would seem to be more than chance that has determined their occurrence. *B. The Red Count.*—Here there has been noted a remarkable improvement since X-ray treatment was begun. The red corpuscles promptly rose during the first two weeks from 2,608,000 to 3,250,000. Then, while treatment was suspended, they remained stationary about that point, but when treatment was resumed they again increased until they numbered 4,000,000. They have practically never since fallen below this point, and have been as high at one period as 4,750,000. *C. The Hemoglobin.*—This likewise has markedly improved, following closely the curve of the red corpuscles. On October 1 it was but 47 per cent. Then it steadily rose until by the end of November it was 75 per cent. It has since remained about this line or slightly above. *D. The Myelocytes.*—These have decreased since treatment was begun, but have never disappeared from the blood. On October 1, 1903, they numbered 48 per cent; on June 25, 1904, when the last count was made, they numbered 27 per cent., and this is the lowest percentage found at any time since the patient has been under observation. *E. The Nucleated Red Corpuscles.*—These quickly disappeared after the X-ray treatment was begun. On October 1, 20 were counted, on November 4 only four, and after that never more than one was seen—all the differential counts being on the basis of 400 white cells counted. In the past three months no nucleated reds at all have been seen.

Bad Effects of Treatment.—None such were at any time observed, except the dermatitis. No such evidences of constitutional disturbance, as Senn mentions in his report, were seen during the progress of treatment of this case; and "high temperature and other evidences of intoxication," such as he describes, never occurred during the months that the X-ray was used.

In conclusion, I desire to say that this case is reported simply as a presentation of facts, not to uphold any theory. Only as more such reports are made by different observers, can we arrive at any just estimate of the value of X-ray treatment in leucemia.

A COMPLETE CASE OF SYRINGOMYELIA.

BY M. G. SCHLAPP, M.D.,
OF NEW YORK;
INSTRUCTOR IN NEUROPATHOLOGY IN CORNELL UNIVERSITY MEDICAL COLLEGE, NEUROLOGIST TO THE OUTDOOR DEPARTMENT OF THE PRESBYTERIAN HOSPITAL, NEW YORK CITY, ETC.,
AND
JAMES J. WALSH, M.D., PH.D.,
OF NEW YORK;
ADJUNCT PROFESSOR OF GENERAL MEDICINE IN THE NEW YORK POLYCLINIC HOSPITAL AND SCHOOL FOR GRADUATES IN MEDICINE.

Syringomyelia is not a very rare disease, though outspoken cases of it always have a more than passing interest. In most cases, however, there is a lack of indication as to the beginning of the pathological process which causes the characteristic symptom. It is generally conceded now that the basis of the degenerative process in the spinal cord is either a congenital malformation of the cord or some destructive lesions consequent upon injury, or some pathological process in early life many years before the characteristic atrophy and sensory symptoms of the fully developed disease. The case that we are about to describe has in its history evidence of the preliminary pathological condition which led to the formation of a cavity or tumor in the cord later in life.

Fig. 1.

Atrophy and dissociation of sensation in area outlined.

The patient was a young woman of about twenty-one years of age, who came to the Out-

door Department of the Presbyterian Hospital presenting well-marked symptoms of syringomyelia in her left hand. With the exception of this condition she is now perfectly healthy, but she recalls distinctly that some fourteen years ago she suffered from an attack of weakness and paralysis in this same arm. She does not remember exactly all the details, but thinks that this came on rather suddenly and at a time when she was perfectly well just before. On close questioning, however, she confesses that she had about the same time what she calls a "rising on her face." This, manifestly, from her description, was a large boil. The possibility of its having something to do with the condition which developed is not impossible, but as we shall see a little later, a direct connection does not seem at all likely.

She remembers that this weakness of her arm came on suddenly, and that she was unable to use her hand at all and especially for such finer movements as picking up pins and the like. Her fingers seem to have been especially affected. The paralysis that occurred, however, involved the whole arm as far as the shoulder, for she could not use the arm at all. Previous to this illness she cannot remember having suffered from any other serious affection, and she does not even seem to have had the ordinary diseases of childhood.

Her arm gradually regained its strength and at the end of three or four months she could use it as well as ever. Before the end of six months no trace at all was left of the paralysis.

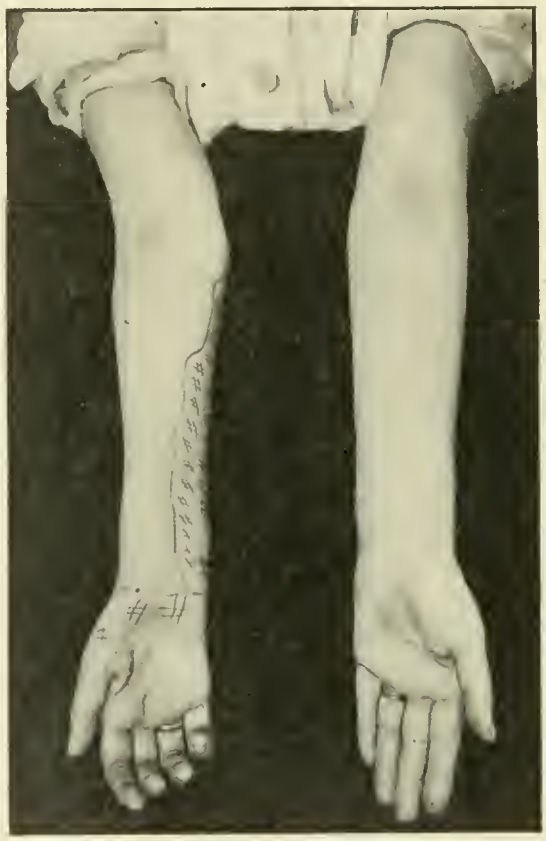
Just ten years later, that is about four years ago, when she was seventeen years of age, she began to notice that her hand trembled considerably after doing any work. She found it practically impossible to hold the fingers still at times. Increasing weakness became manifest and she found it difficult to do many things that she had been familiar with for years and had gradually to learn the use of her left hand to replace her right. Her hand was inclined to be cold and during cold weather was tremulous and very weak. During the winter time it was often so numb that she could not use it at all.

Three years ago she noticed a wasting of the muscles of the hand, especially those of the ulnar side of the hypothenar eminence becoming flattened. This wasting of muscles spread with gradual diminution of the size of the thenar eminence and with distinct wasting of the interossei muscles. Her fingers began to be overextended in the proximal phalanges, though with flexion of the distal phalanges giving a characteristic appearance of beginning claw hand.

The present condition as regards the muscles shows the flat hand of atrophy of the hypothenar and thenar eminences, both having disappeared, and the distinct beginning of main en griffe. In the affected area which extends somewhat above the elbow there is some temperature sense disturbance, but this is comparatively slight. The pain sense, however, is seriously disturbed, and over an area some eight inches long on the ulnar side of the forearm there is complete analgesia. In this same area she feels touches very well and recognizes heat better than cold. This dissociation of sensation points, of course, to disturbance of the sensory tract immediately surrounding the central canal in the lower cervical region and makes it evident that the diagnosis of peripheral symptoms of syringomyelia.

The interesting problem in this case is the etiology of the condition. It has generally been

Fig. 2.



Atrophy and dissociation of sensation in area outlined.

conceded that syringomyelia develops either on a basis of some congenital malformation of the cord or on a hematomyelia, either spontaneous or traumatic. Even where the predisposing element in the case is a congenital lesion it is usually considered that a hemorrhage taking place into the cord constitutes the first step in the further progress of the case that eventually leads to the appearance of the characteristic peripheral symptoms of syringomyelia.

The occurrence of the first paralysis of the arm for fourteen years before the present condition and over ten years before the first symptom of syringomyelia was noticed, seems to make it

clear that we are not in the presence of a congenital malformation as the basis of the condition which has developed. The complete recovery from the first attack and the long interval of absence of symptoms would seem to preclude the impossibility of there having been a serious defect in the cord which predisposed it to a hemorrhage or to some other pathological lesion at the time of the first set of symptoms.

The symptoms that developed on that first occasion point to the occurrence of a hemorrhage or thrombosis or embolism. To consider them in their reverse order, embolism seems unlikely because the source of it would usually be found in some affection of the endocardium and there is no history of anything like that, and an examination of the heart at the present time reveals no signs of an old endocarditis. With regard to thrombosis, the question is less easily disposed of. At the time that her first set of symptoms developed she was suffering from anemia. She has, indeed, during the most of her life, been rather poor in blood. It is well known how often it happens in anemic cases that a sort of spontaneous thrombosis occurs. If the blood vessel to a portion of the cord were shut up in this way the result would be a necrosis of surrounding tissue quite as effectually as if there were a hemorrhage.

It has come to be usually considered, however, in these cases, that a hemorrhage is the most likely preliminary lesion on which the subsequent developments take place. This may be either spontaneous or traumatic. Spontaneous hemorrhages are quite possible and have been noted in a number of cases. Often there is a suspicion of trauma, but this cannot be determined, owing to the defective history. If a hemorrhage be supposed to have occurred in this case, there came as a result an overgrowth of connective tissue which contracted into a scar. The irritation set up by this led to the development of gliosis of the cord, affecting mainly that portion of the cervical cord lying around the spinal canal on the left side. This would afford a very satisfactory explanation of the condition which has now developed.

With regard to the possibility of an infection from the boil on her face, it seems to have existed at the time of the primary paralysis—it may be said that if there were an infectious embolus at that time in the cervical portion of the cord, it would surely have caused secondary infection in the neighboring area, and this would have produced a more lasting and more extensive set of symptoms than was observed.

There is one important point in the treatment of these cases. Owing to the dissociation of sensibility they are likely to suffer from various lesions, especially from burns and at times from rather severe trauma in the affected part. Owing to the lowered condition of the trophic nerve supply to the part these injuries heal very slowly and are rather obstinate to all ordinary treatment. It is important then to warn patients suffering from beginning syringomyelia of the necessity of taking the greatest possible care of the affected member, in order to avoid the accidents to which it is liable, because of the disturbed sensory condition of the part. Beyond this there is not very much to be done and of course the outlook is absolutely unfavorable, since there is no hope of any decided improvement, to say nothing of cure.

THE CONVEYANCE OF YELLOW FEVER.[1]

BY HENRY R. CARTER, M.D.,
OF BALTIMORE, MD.

I will say nothing of the history of my subject. It is interesting to read the many theories advanced for the causation and prolongation of yellow fever; especially the arguments for its conveyance by "infected air," and its "spontaneous origin" under specified conditions. Nor is such a review altogether unprofitable, but the interest is speculative now rather than practical, and it would take time. I cannot even take the time to give the history of the evolution of the doctrine I shall advocate, although I should like to show you how blind we were to Dr. Finlay's arguments until Reed's demonstration compelled us to see.

I simply propose to announce what I think to be *the true doctrine* of the propagation of yellow fever, and to give briefly my reasons for the faith that is in me.

This is the proposition—the "creed," so to speak, of the doctrine: *Yellow fever is conveyed from the sick to the well by a mosquito host, the Stegomyia fasciata, contaminated by feeding on the sick man; and, in nature, it is only thus conveyed.*

It does not seem necessary to discuss the first part of this proposition, as I am sure you all accept the statement that yellow fever *is* thus conveyable. It is a positive proposition and thus admits of positive evidence, and that evidence is satisfactory and abundant. The American Commission, of which Reed was chairman, reported, first and last, 12 cases thus conveyed; Reed and Carroll, two; Guiteras, eight cases; Parker, Porthier, and Beyer, at Vera Cruz, one case. The second party at Vera Cruz, one case; the Pasteur Institute Commission at Petropolis, four cases; Ribas and his confrères at Rio Janeiro also reported successful experiments, but I have not seen their report and do not know the number of their cases. Indeed, all who have tried to convey yellow fever in this manner have succeeded. I do not think, then, that any of us doubt that yellow fever is thus conveyable.

Note, please, the conditions under which this conveyance occurred in the experiments noted: (1) A particular kind of mosquito was used—*Stegomyia fasciata.* (2) It bit a patient in the

[1] Read before the Texas State Medical Association, April 27, 1904.

first three days of yellow fever. (3) It was kept a considerable time—twelve days was the shortest time—and then bit the well man.

After once acquiring the power of conveying yellow fever, for which a certain time after biting the sick man is necessary, the mosquito seems to retain the power indefinitely; at least one of Reed's mosquitoes conveyed yellow fever fifty-nine days after feeding on a yellow fever patient.

Given the above conditions, yellow fever was produced with reasonable constancy. A few men, very few, were found to be immune to this method of conveyance, and not every mosquito bite conveyed yellow fever even to those who subsequently succumbed to mosquito bites.

Let us inquire into these conditions one by one and see if we can tell what are the essentials of this method of propagation of yellow fever.

1. The kind of mosquito. So far, except one trial of *Culex pungens*, only the *Stegomyia* has been used for experiment. It seems idle then to speculate if some other genus or species of mosquito will not also act as host. Analogy would lead us to suspect that some other species of *Stegomyia* would do so, but that no mosquito not of this genus would. The genus, and this species of it, is widely distributed in hot countries. Obviously we cannot exclude such species as are found in places where yellow fever does not spread when introduced. And here let us notice that if yellow fever is conveyed by only one genus or species of mosquito, then it is conveyable only where and when that particular mosquito is found, and is active, and that arguments concerning its conveyance drawn from the habits of *other* mosquitoes are valueless, unless these habits are common to the *Stegomyia* also; and the habits of the *Stegomyia* are in many respects different from those of other mosquitoes.

Nor does the presence of mosquitoes in a place in any wise imply that yellow fever can be propagated there, unless they are *Stegomyiæ*. I would not state facts so obvious unless I had seen the need of it. I was asked, "How can you say that a vessel a few hundred yards off shore is safe from the invasion of infected mosquitoes, when you yourself say that you have seen swarms of mosquitoes come aboard a mile out at sea?" Now the "infected mosquitoes" *Stegomyiæ*, and the "salt-water" mosquito, a *Culex*, that boarded me off shore were a different thing altogether.

A gentleman, an excellent physician, too, asked why, if mosquitoes conveyed yellow fever, could one explain that a certain hospital where yellow fever was treated remained uninfected, "although being close to the marsh it was swarming with mosquitoes." There was no evidence to show that these were *Stegomyiæ*. Indeed this variety is not, as a general thing, found in marshes.

2. In all the experiments the patient was bitten in the first three days of yellow fever. Is this the limit of time during which he can infect the mosquito? You can see what a very important point it is to determine this; because if it be true, a patient after this time can no longer communicate the disease even if bitten by a mosquito. The only experiments on this matter are those of the Pasteur Institute Commission. They injected blood from three cases of yellow fever, each one in the fourth day of the disease, into three subjects, it having been found that the disease was conveyed quite certainly by this method. None of these subjects developed yellow fever. One of them was shown to be susceptible to yellow fever by being bitten afterward by an infected mosquito. This commission concludes from this that the power of the patient to produce infection lasts only three days. Yet this seems to me too absolute a conclusion for the number of observations made. Unquestionably the blood of *these* patients did not convey yellow fever, but I would prefer to see more experiments on this matter before I regard it as settled; and it is a very important one for the sanitarian. Important, because we wish to isolate the patient *only* while infective, and if three days is the limit, we will not isolate him longer. Not only for his sake, but for our own. My experience has been, and I think all health officers will confirm me, that restrictive measures of sanitation, especially if domiciliary measures are used as well, are hard enough to carry out any way, and that the less we require, provided it be all that is necessary, the better will the work be done. The enforcement of unnecessary measures of that kind is generally at the expense of some essential. As of old, the tithing of mint, anise and cumin leads to the neglect of the weightier matters of the law.

3. How long must the mosquito wait after biting the yellow fever patient before it can communicate yellow fever? How long does it take for the infected mosquito to become infective?

Now, before Reed's work in Cuba, I had determined the existence of a period of time—and a considerable period of time that must elapse after the development of a case of yellow fever in an uninfected place before that place became infective. During this time yellow fever could not be contracted in this place. This period, the length of which I could only approximately determine, I had called the "extrinsic incubation" of yellow fever. I did not know the explanation, yet the knowledge of *the fact* was of great service to me in epidemic work. It was, of course, the time that it takes for the mosquito after biting the sick man to become infective. This time depends on the temperature—as do all of the processes of, and in, the mosquito—being longer in low temperature. The shortest time in which this power of conveying infection has been manifested in the experimental cases, was twelve days. It was usually decidedly longer than this in Reed's experiments, most of

which were in the winter. The twelve day case was in August. It seems to be accepted that twelve days is the shortest time in which an infected mosquito can come to be infective, and this agrees with my own crude determination of the minimum period of extrinsic incubation—"somewhat over ten days" and yet I cannot think that this has been *experimentally proven*. Not enough attempts have been made during hot weather with mosquitoes for less than twelve days. The determination of the minimum of this period is of interst, but not of great importance.

I am sorry to confess that we have not found the micro-organism of yellow fever, although it has been assiduously searched for both in human blood known to contain it, and in the mosquito; yet some direct observations have been made on it. In the blood, at least, it exists in an ultramicroscopical form, as was first shown by Carroll working on lines laid out by Reed and himself. He found that blood serum filtered through a Berkenfeld filter, would still produce the disease. This was confirmed by the Pasteur Institute Commission and, in my opinion by the working party at Vera Cruz, the Pasteur Institute Commission found that serum passed through a Chamberlain bougie B would convey infection, while that passed through a bougie F would not, thus determining within the limits the size of the smallest of the infective germs. I say, "the smallest infection germs" advisedly, because they *may* exist in the blood in different forms—as the *Plasmodium malariæ* often does—and only the small ones pass the bougie B.

It is worthy of note that the direct injections of blood and serum, filtered and otherwise, seem to differ from mosquito inoculations in the length of the period of inoculation. Of 24 mosquito inoculations in normal individuals, of which the period of inoculation was accurately recorded, the shortest was two hours less than three days, and the longest two hours over six days, and all save these two were between three and six days. With this agrees my own observation of the period of incubation of 12 cases of yellow fever, naturally contracted, each with a single, short exposure—all of which gave incubations of from three to six days. Now in the 14 cases of blood and serum injections, the time varied from one day and twenty hours to twelve days and eighteen hours, three of the cases being eight days and five hours, 9½ days, and 12¾ days. Whether there is a real difference, or whether these mosquito inoculations and my observations *happened* to have no very long or very short periods of incubation, I cannot say. Only as we have 36 of these cases recorded, and this is the natural way of conveying the fever, I would rather base my sanitary measures on the data from them than on the results of direct injection of blood.

The organism is very easily killed; blood heated to 55° C. for five minutes is no longer infective, and it soon dies in blood exposed to the air, although blood five days old covered by oil of vaseline is still infective.

So much for this positive part of our proposition, that yellow fever *can* be conveyed in the manner stated.

The second part of it is different in its very nature. It is a *negative* proposition. To say that "yellow fever is only conveyed by a mosquito host," is saying that it is not conveyed in any other way—in any one of the many other ways which might be claimed as the true one—and, to proceed logically, one should examine the evidence advanced for every such way of conveyance and demonstrate its futility. There are two reasons why I do not do this: (1) because it would be almost unending, and (2) because, as I do not believe that it is conveyed in any other way, I might not state the arguments for the affirmative fairly. To demolish a man of straw of one's own making, is seldom convincing. Yet I will give a few reasons why we should accept the conveyance by a *Stegomyia* host as the only means by which it is naturally conveyed. I say "naturally conveyed," meaning the way yellow fever is contracted naturally during epidemics. The disease can be conveyed, as we have seen, without the mediation of a host by the hypodermatic injection of the blood of the patient, but that surely is *not* a natural conveyance.

Analogy.—Of such diseases as have been fully investigated, all that are conveyed by living hosts are conveyed naturally in no other way. This is a biological law.

Familiar illustrations are malarial fevers and Texas cattle fever, which is very like yellow fever in its epidemiology; and there are a number of diseases of the lower animals thus conveyed, and for all this law holds. The facts observed of the natural propagation of yellow fever agree with this theory and are explained by it.

For instance, the fact that the disease is not directly propagated from the sick to the well, that it is propagated only by means of an infected environment, that a man sick of yellow fever may infect his environment.

By our theory he infects the mosquitoes which bite him, and the presence of these infected mosquitoes constitutes the infected environment.

The existence of infectible and non-infectible places.

An "infectible" place, as you know, is one which, if cases of yellow fever be introduced therein, becomes infected—*i.e.*, capable of inducing yellow fever in those who visit or live there. A "non-infectible" place is one which will not become infected even if cases of yellow fever be introduced. In such a place yellow fever is not a transmissible disease. The theory of conveyance by a host would explain this difference by the presence of the proper host (*Stegomyia*

fasciata) in the one and its absence in the other.

The relation of the spread of yellow fever to cold weather, altitude and excessive dryness. The very conditions under which *this mosquito* —mind you, I do not say "mosquitoes"—thrives best suit the propagation of yellow fever.

The close correspondence of the periods of incubation from infection in the natural way—12 cases observed by myself—with the periods of incubation after mosquito inoculation—24 cases. Yellow fever caused by the hypodermatic injection of blood or strained serum from a yellow fever patient has not shown the same agreement in its period of incubation with that naturally contracted. It may be because this is not a natural method of conveyance.

The existence of a considerable interval seldom under two to 2½ weeks, between the infecting and the first "secondary" cases of yellow fever. I mean that when a case of yellow fever, contracted elsewhere, develops in a non-infected place, no case will develop from the first one until *after* about two weeks, and that then we are apt to have a considerable number together as our first crop. Now this time is decidedly longer than the period of incubation of yellow fever, and since it is an invariable phenomenon, it can only mean that the place requires a certain time after receiving infection from the sick before it becomes capable of inducing yellow fever in others. This of course is the "extrinsic incubation" we have spoken of before, and its usual minimum duration, which had been fixed by observations of yellow fever naturally occurring as somewhat in excess of ten days" (the first secondary cases usually occurring in the third week) is too close to the period, twelve days as a minimum, which Reed observed between the date of the feeding of the mosquito on the yellow fever patient and the date on which yellow fever was conveyable by the same insect, for those periods to be due to different causes. That cause in Reed's cases was the incubation in the mosquito. The same phenomenon is observed with malarial fever—*i.e.*, a certain time must elapse from the infection of the *Anopheles* by the ingestion of the *Plasmodium malariæ* before it is capable of producing the disease in those whom it bites, and so with other diseases caused by parasites conveyed by living hosts.

Indeed, this phenomenon and the fact that some places are infectible, and some not infectible by a yellow fever patient, with no reason which we could assign for the difference, are, taken together, scarcely capable of any other explanation than conveyance by the host.

Indeed I do not know one single fact established concerning the natural propagation of yellow fever which does not agree with the doctrine of its conveyance by the *Stegomyia fasciata* as a host.

3. Measures founded on this doctrine have given the results which were to be expected of them if it were true. And this I hold to be most convincing evidence.

In 1899 and 1900 "campaigns of cleanliness" were waged against the yellow fever in Havana. All the money that could be called for was forthcoming, and all the men. Skilled engineers were in charge with the whole force of military power behind them. In 1899 General Ludlow was in command and Major Davis was chief sanitary officer; in 1900 it was General Wood and Major Gorgas. And I can give you my word that the work was well done. Havana was as clean as a cobblestone-paved city can be kept. We began, too, with a city almost free from yellow fever. There had been but 31 deaths from yellow fever among civilians the year ending March 31, 1899, and there were only five more in August.[1] The fever then spread, and we had that year to March 31, 1900, 111 deaths among the civil population. Less than normal, but just the same number as in 1885, when no sanitary measures were used. In 1900 the work was, probably, better organized and was certainly as well done, yet the deaths that year were 301, although this includes some among the military—say 12 or 15. The average civil death rate from yellow fever in Havana for the ten years prior to the war was 211 per annum. We had then this year more deaths among the civil population than normal in Spanish times; nearly one-third more. Indeed 1900, after all our work, gave a *higher civilian mortality than any one of the ten years prior to the war except 1893.*

Now, during this time Havana was as clean as it could be made. Patients were isolated to some extent; all whom we could get to go were moved to hospitals—probably 75 per cent.—and the premises carefully washed down with bichloride of mercury, and the fabrics disinfected by steam or bichloride or boiling. Yet, as I tell you, we had an epidemic. So far as yellow fever was concerned, the sanitary work was a failure. The next year, the plan was changed. The *Stegomyia* was accepted as the only means of conveying yellow fever and all effort was based on this belief. All cases of yellow fever were screened as soon as found, and they were found early and the screens were kept in place too. If the patient went to the hospital, the house was immediately fumigated with either pyrethrum or sulphur. If he did not, it was screened and fumigated as soon as possible; the houses adjacent being also fumigated. This was the key of the plan: (1) To keep mosquitoes from the patient. (2) To kill all mosquitoes which had had access to him.

There was, also, a general war waged against all mosquitoes in town, draining and oiling pools of water; emptying, covering or oiling water in containers. The presence of mosquito larvæ on premises was made a public nuisance and punished by fine.

These measures unquestionably did good and there was certainly a tremendous fall in the mortality in all malarial fevers; but the essential of the work for yellow fever was, as I have said, *to keep mosquitoes from the patient and to kill those which had had access to him.* Nothing else was done. The bedding and clothing of the sick were not touched, nor the bedding and clothing in the houses where they were taken sick. Now the result.

Yellow fever disappeared. There were about the usual crop of cases in the spring, but there was no spread. Some were introduced from Santiago de la Vega and other places outside of Havana, but there was no spread to amount to anything. Cases, a few, were brought on the vessels from Vera Cruz, taken to the yellow fever hospital and screened, and there was no spread. Gentlemen, this was not luck. It was not accident. Havana had had yellow fever for 140 years. It was freed from it in the summer of 1901, *by the measures taken.*

I am glad that the same man, Dr. Gorgas, had charge of the sanitary work in both 1900 and 1901, so that everything should be the same except the *plans of the work* and the *difference of the results*—in 1900 a failure; in 1901, a brilliant success. Could this have happened if there had been any other means of conveying yellow fever except the insect host? What else will screens exclude? What else will insect powder kill? Remember the bedding, clothing, etc., of the patients were not touched.

There has been no yellow fever in Havana since—that is, none contracted there. You know that Havana is in weekly communication with Vera Cruz and other Mexican ports, receiving a considerable number of passengers by each vessel. How has she kept infection from being introduced from these ports? There is a maritime quarantine at Havana just as at all seaports among civilized nations. As Dr. Finlay directs it, the quarantine for yellow fever is naturally based on the assumption that the *Stegomyia* is the only agent of conveyance of that disease to man. Passengers not immune to yellow fever are retained in quarantine across the bay five days from their last presumable exposure to yellow fever before they are allowed to enter the city. Vessels which may be infected with yellow fever (*i.e.*, which may have infected *Stegomyiæ* on board) are not allowed at the wharves or to be boarded by non-immunes until after fumigation to destroy mosquitoes.

Baggage of all kinds from Vera Cruz, Tampico, and Merida, even that of people sick of yellow fever, is passed without disinfection.

People arriving with yellow fever are taken at once in an ambulance screened with mosquito wire, to the yellow fever hospital. This is a ward screened and with double screen doors in the general hospital in the city of Havana. A number of such cases have been thus treated and there has been no spread. No spread was expected by those in charge, and I venture to promise that there will be no spread as long as the present system is carried out.

Look at this quarantine! With passenger traffic, from infected ports, with its protective measures directed only against mosquitoes; with absolutely no disinfection of baggage and yet giving a perfect result.

The same regulations had been in effect at a number of our southern ports, those of Virginia, North Carolina, Georgia, Florida, and Mississippi, the past year—for the United States regulations are also based absolutely on this doctrine, and require only what is given above—and with the same result. Could this be if yellow fever were conveyed in any way except by an insect host? Could it be if fomites could convey yellow fever?

Fomites! A while ago I said I knew of no fact in the propagation of yellow fever which was not consistent with the doctrine of its propagation by a host. I am sure some of you thought of "fomites" then. I promised not to set up a man of straw and demolish him, and yet, as I used to believe in this means of conveyance myself, it may be that the arguments which convinced me that I was wrong may have weight with some one who believes as I did. Obviously, if yellow fever can be conveyed by formites, the doctrine that it is only conveyed naturally by a mosquito host, is untrue.

I believed it, the conveyance by fomites, (1) from the analogy with other infectious diseases, smallpox, measles, etc., and (2) because everyone else did. The doctrine was not disputed and I did not examine the evidence for it critically. Yet even before Reed's first paper, I had come to rather more than doubt—almost to disbelieve—that *fabrics* conveyed yellow fever, although I *knew* that *ships* did. My mind was not changed simply to accept this theory. In the first place, all the yellow fever outbreaks which I myself could trace, a man sick of yellow fever was the starting point. There were many which I could not trace. In some such outbreaks, fabrics from infected places had come in, and in the vast majority no such fabrics could be traced. None of the reported cases of conveyance by baggage which I could personally investigate, excluded other means of conveyance.

Then I found that for the 220 years preceding 1899, the baggage from Vera Cruz, Havana, and Santiago de Cuba on vessels arriving at New York, unless with yellow fever en route, entered without disinfection. The amount of this baggage from Havana and Vera Cruz was large, and it was not impossible but that much of it came from houses infected with yellow fever, and much of it was not clean. All of this baggage was presumably opened at the custom house at New York, and it was opened at hotels there and at Saratoga, and no yellow fever was reported among the customs inspectors in New York, or at the hotels during this time.

The baggage going from the same ports to Spain for the twenty-nine years preceding 1899, was even more to be considered. Its amount was enormous. Much of it must have been foul. Yet no yellow fever was reported in the Peninsula since the epidemic of 1870.

Of course, negative evidence is convincing only in proportion to its mass, and that a piece of baggage, or 100 pieces of baggage, from an infected place did not convey infection to those exposed to it, means little, yet the amount of this baggage was so large—I cannot estimate it at less than that of 300,000 persons from Havana alone, not to count Vera Cruz and southern Cuba —that we must claim that a very large amount of baggage from infected houses had been introduced into New York and the Spanish towns; that numbers of susceptible people had been exposed in these places under various conditions, but had *not* contracted yellow fever.

To me the mass of this evidence was sufficient to be convincing, and I counted it *proven* that baggage from Havana and Vera Cruz would not convey yellow fever to people in New York or Spain, nor could I deny that baggage did not convey yellow fever in New York or Spain, but it would do so in the South. I knew that yellow fever was communicable from a sick man only by infecting his environment and hence only in an "infectible locality," but the contrary had always been the teaching for fomites. That infection could be *directly* conveyed to man by fomites is the doctrine which had been universally taught. All the instances reported of conveyance by fabrics of which I had cognizance were either explicitly ascribed to, or explicable by, this direct conveyance. Now, if the "infected" fabrics could convey yellow fever directly to men, obviously they would convey it to susceptible people who come into direct contact with them in any place whether the locality be "infectible" or "non-infectible." Therefore, as against the possibility of direct conveyance of yellow fever from fabrics to men, the data from New York and Spain, which I have given above, if conclusive for those places, were conclusive against such conveyance in places known to be "habitually infectible."

As to the positive instances of conveyance by baggage, which had been reported, none that I was able to inquire into personally certainly excluded other methods of conveyance. The reporter begins with the assumption that yellow fever is conveyed by fomites, and as soon as he can show the introduction of fomites from an infected place, he is satisfied. He looks no further for any other source of infection. Strange to say, the best-attested cases I came across were not those of conveyance by *packed baggage,* but by *clothing worn on the person,* sometimes for a number of hours, through the sun and air, which was against all other experience of this disease.

Also it is common sense that when there is a great mass of negative testimony on a subject, all tending one way, we may not accept a moderate amount of positive evidence in rebuttal unless its data be conclusive, and I thought the evidence of the Cuban and Mexican baggage great enough for this rule to apply.

Note, too, that the argument for conveyance by fabrics was really a negative one. The reporter says "there was no possible source of infection except the fomites." He means that he knows of no other. Exactly the same argument was used, and logically, for the spontaneous origin of yellow fever. Cases were cited for which no exposure to *any* source of infection could be made out, and the statement was made that there *was* no exposure. From this, if admitted, the admission of the "spontaneous origin" of the cases was a necessary consequence. These cases were (indeed are) not a few. They were reported with as much detail, and with as much care, and by as good men, as those for which no exposure except to fomites was known. The argument for the spontaneous origin of yellow fever, and that for its conveyance by fomites, both depend on our accepting that there were no exposures unknown to the reporter. They stand or fall on the same class of evidence.

As to the cases of infection carried by clothing worn on one person, which I have said seemed the best stated of all which I had cognizance, I know that a large number of passengers had been coming during all seasons of the year from 1888 to 1898—ten years—from Havana to Key West and Tampa, with no disinfection of the clothing they are aware of, and yet Key West and Tampa had kept free from yellow fever. It was not possible that the thousands who thus came over should have carried no infection if clothing worn on the person could carry it. There must then be some other explanation for the few cases reported in the United States. I think, then, that I was right to count the conveyance by fabrics as "not proven" on this evidence.

In addition I did not have what you now have: (1) The experiments of Reed, of Ross, and of the Pasteur Institute Commission. In these a number of persons were exposed for days and nights to bedding and clothing used in every conceivable way about yellow fever patients. None of these people developed yellow fever from exposure, although a number of them did when subsequently bitten by contaminated mosquitoes. To be fair, I wish to admit here what the fact that Reed's experiments with fomites were done late in the year detracts from their value. This, however, does not apply to the other two. (2) The freeing of Havana from yellow fever by Gorgas, although the clothing and bedding were not disinfected. (3) The continual experiment which the Havana quarantine and many of our own stations have been giving us in letting in baggage from yellow

fever ports without any disinfection, and yet with no introduction of yellow fever.

Note that in these last two the fomites which did not convey infection were in infectible places in the yellow fever season.

If I had had all this evidence in addition to that which convinced me, I would, I think, scarcely have considered conveyance by fomites worthy of discussion. And that whether I knew of any other method of conveyance or not.

Let us see what we have said. There is no question in any man's mind that the mosquito *Stegomyia fasciata,* acting as a host, does convey yellow fever from the sick to the well. That this is the only method of conveyance, the argument is: (1) The analogy of other diseases conveyed by living hosts; (2) that the facts observed of the natural propagation of yellow fever agree with this theory; (3) that measures based on this theory have given the very results which they should have given if the theory were true; (4) no other natural method of conveyance is proven.

ENDOTRACHEAL MEDICATION.[1]

BY J. J. RICHARDSON, M.D.,
OF WASHINGTON, D. C.

The successful treatment of many of the diseases of the respiratory organs, notwithstanding the rapid advances within recent years in their pathology and bacteriology, is a problem yet unsolved. Any advances along these lines are of more than passing interest, not only to the profession, but to the laity as well. While the surgeon has been penetrating all the cavities of the body with impunity, the practical therapeutist has been none the less aggressive, and among other things has taught us to look upon the larynx as an open door to a new field of medication.

We have in intratracheal injections a valuable method of treating many of the inflammatory and infective diseases of the lower respiratory tract. Those who do not employ it are depriving themselves of a most effective means of medication. It is simple, safe and practical. Diseases below the larynx, owing to the prevailing opinion of their inaccessibility and sensitiveness to local treatment have been treated mostly by internal medication. Sprays and vapors have been used to a considerable degree and can be made to penetrate quite deeply, but the quantity of the drugs reaching the parts is so small that as a rule little real benefit results. We all favor the local treatment of diseases of the nose, pharynx and larynx, and it is only rational that similar changes taking place in more remote parts should not be treated along the same lines and with equally satisfactory results. It is entirely practicable to medicate the whole bronchial area and reach portions of the lung by absorption through the pulmonary lymphatics.

The first impression naturally is that violent coughing would be produced, but this is erroneous. Indeed, it usually produces no more disturbance than an ordinary application to the nasopharynx or larynx. The usual objections urged against it are groundless. Some claim that it possesses no therapeutic value, others that serious interference to the function of respiration may result, that it produces nervous shocks, spasm of the glottis, etc.

The technic of the injection is simple. The patient should be seated in front of the operator, the light placed along the side of the head, the mouth held wide open, the tongue protruded and held firmly by the patient. With a frontal mirror the light is focused on the pharynx—a laryngoscope placed in the illuminated zone which gives the image of the epiglottis and glottis. The canula of the syringe is then directed over the epiglottis, and during an inspiration by making a sort of see-saw motion of the syringe from below upward, is made to penetrate between the vocal chords and pass the first rings of the trachea. The syringe is then relieved of its contents, while the patient inhales slowly and deeply. This is the all-important point to be observed in making successful injections. Only rarely is severe coughing produced, and when it does occur is often due to the unskilful introduction of the fluid.

In hypersensitive throats it is frequently necessary for the first few treatments to use a two-per-cent. solution of cocaine as a spray to overcome the pharyngolaryngeal reflex. There are patients who can be successfully injected by simply depressing the tongue and guiding the syringe directly over the tip of the epiglottis into the larynx and trachea. I have practised this method frequently in cases where the pharyngeal reflex was not hypersensitive with just as satisfactory results as where the mirror was employed. I have had no experience in treating children by this method.

The success in making the injections will depend in no small measure on the selection of the syringe. The one which I have found most satisfactory, and the only one, is Shradel's, manufactured by Tiemann & Co., of New York. It consists of a glass barrel inclosed in metal and having a spiral spring attached to the piston. When the syringe is filled with the liquid for injection, it is relieved of its contents by gentle pressure with the index finger on a small spring, that allows the liquid to flow out quickly or slowly, according to the will of the operator. The canula is about eight inches in length, and is of the proper curvature for its introduction and passage through the larynx.

The selection of the medicaments for injection is of paramount importance. In general they should be antiseptic, stimulating, non-irritating and soluble in the vehicle employed. In the early days of intratracheal medication watery and mucilaginous solutions were used, but they proved too irritating. Within recent years oily solutions have been employed, with results that

[1] Read before the Clinical Society, Washington, D. C., April 11, 1904.

warrant their continuance. The therapeutic agents that I have used mostly have been the volatile essential oils eucalyptus and thyme, combined with menthol, camphor, creosote, iodoform or orthoform, according to the indications of the case, with sterilized olive oil as a vehicle. By the use of the oils in this way, we get a *double action.* They are absorbed and then re-eliminated by the pulmonary mucosa—thus insuring modification of the whole subglottic breathing tract.

Various experiments have been conducted on human beings and inferior animals, demonstrating the rapid absorptive and eliminating function of the bronchial mucous membrane. The injections should be given daily, and one or two drams of the liquid may be injected at a time. I frequently give two or three injections at one sitting. A great factor in favor of this treatment is that it does not disturb digestion or interfere in any way with other treatment which it may be desirable to carry out in conjunction with it. The diseases treated have been bronchitis, bronchial asthma, tracheitis, bronchiectasis, and pulmonary tuberculosis. Its greatest field of usefulness is in the treatment of bronchitis. The mixture which has proven in my experience the most beneficial in this class of cases is five per cent. campo-menthol with eucalyptus and thyme and sterilized olive oil, or a highly refined bland petroleum. In the acute congestive stage it produces coughing, but as a rule it lasts only a few minutes, and the soothing effect which follows is very grateful to the patient. A few injections will frequently entirely relieve the cough and expectoration.

There are a great many people who have the so-called "winter cough," which develops as regularly as autumn comes, and in spite of all cough mixtures, persists till the warm, balmy days of spring. All these patients have a chronic bronchial catarrh, and improve more rapidly under the injections than any other method of treatment with which I have had any experience. No other treatment gives such prompt relief in the chronic bronchitis of alcoholics and the acute attacks which so frequently follow dissipation. Again we have the bronchitis or "bronchial weakness," we may term it, in smokers and "high livers." These patients are not successfully relieved by internal medication, but the cough, expectoration and dyspnea, a symptom which they almost all have—can be best controlled by direct medication. It is not every case of bronchitis, however, that is adapted to this treatment, nor will it ever entirely replace the older methods, but it does offer an additional means of medication whose usefulness I am sure will be appreciated as experience with it increases. In tracheitis where the laryngoscope shows the mucous membrane to be congested—the presence of scales of adherent mucus, and where there is a dry hacking cough, the injections are just as efficacious as in bronchitis.

In a few cases of bronchial asthma the acute symptoms were quickly and satisfactorily relieved, and there was notable lessening in the frequency of the attacks. The addition of a few minimums of compound tincture of benzion and chloroform to the menthol, eucalyptus and thyme is valuable. I have treated three cases of bronchiectasis by injections of the oils with the addition of iodoform, in which there was for a time marked relief following the treatment. The mucopurulent expectoration diminished, and there was a rapid decrease in the cough.

As to tuberculosis: Intrapulmonic injections, like so many other treatments for this terrible disease, have not proven by experience to be all that was hoped for in the beginning. In most cases nothing more than temporary relief can be expected. The injections have no specific effect. I am led to this conclusion by carefully observing the results of treatment in forty-five cases of the disease where the diagnosis was confirmed by bacteriological examination. I can recall a few instances where for a time the tubercle bacilli disappeared from the sputum. It was only temporary. We have in it, however, a means of alleviating the local and general symptoms of the disease in many cases better than by the internal administration of drugs. It controls the cough, decreases the expectoration and changes its character. In this way secondary infection is overcome to a great degree with a corresponding decrease of the fever and the night-sweats. Most of the patients will speak of a general sense of relief following its use. The breathing will become easier and the feeling of constriction about the chest so frequently present is greatly relieved. Many of the patients have spoken of this and the relief lasts from twelve to twenty-four hours after the treatment. It doubtless results from the local anesthetic effect of the menthol on the nerves of the bronchial mucous membrane.

Of course the dyspnea resulting from pulmonary disorganization of advanced disease is not benefited. Where there is laryngeal complication I believe the benefit is most marked, and in every case we are warranted in using it. Owing to the sensitiveness of the parts it is well to add to the compound of volatile oils, menthol and creosote, soluble hydrochlorate of orthoform for its local anesthetic effect as well as for its antigermicidal property.

Injection of Osmic Acid for Tic Douloureux.—The case of a woman, seventy-one years of age, who presented an intense tic involving the right side of the face, is reported by J. R. Eastman (*Jour. Am. Med. Ass'n*, Sept. 24, 1904). The attacks gradually worse for the past twenty years, and the usual remedies had been found ineffectual. A two per cent. solution of osmic acid was then injected into the supra-orbital, infra-orbital and dental nerves, in the manner recommended by Dr. J. B. Murphy. Ten drops of the solution were injected into each branch and two to three drops forced into the perineural fat around the nerves at their foramina of exit.

MEDICAL PROGRESS.

SURGERY.

Dermatitis of the Hand After Use of X-ray.—A severe case occurring in a physician who had employed the rays continuously since 1897, is reported by R. Mühsam (*Arch. f. klin. Chir.*, Vol. 74, No. 2), During the winter of 1900-01, a dermatitis was observed, accompanied by scaling of the skin and localized temperature. Patient then ceased to employ the rays. The condition nevertheless grew worse, the nails became brittle and showed irregular growth, the skin was dry and the hair fell out. The index finger of the right hand was most affected. Here a paronychia resulted and the nail had to be removed. The wound failed to heal and an ulcer remained, which was very painful and gradually extended, causing so much discomfort that the patient begged amputation of the finger. This was done, but the wound did not heal until nine weeks later. Examination of the digit microscopically showed the most marked changes in the vessels. The intima was very much relaxed, the endothelium swollen, and the surrounding tissue was markedly infiltrated. The changes amounted to an obliterating endarteritis. In the partial or complete obliteration of the vessels must be sought the reason for the slow healing of the ulcer.

The Treatment of Chronic Colitis.—The treatment of this condition should essentially be based on the etiological factors, according to B. V. Beck (*Arch. f. klin. Chir.*, Vol. 74, No. 1). He thinks that the diagnosis of chronic colitis due to a nervous state is insufficient, and the latter is usually the result of the colitis itself. Among 500 cases observed by the author, he found chronic inflammations present in the neighborhood of the colon in 394, and the cure of the colitis depended more or less on their removal. Of these the most frequent were perityphilitis, diseases of the gall-bladder and stomach, and lesions of the female genitalia. The cause of the colitis may also be found in local lesions—carcinoma, tuberculosis, or actinomycosis. In several severe cases after the failure of all other methods of treatment, the writer employed operative means, by which he established an anastomosis between the lower end of the ilium and the sigmoid flexure, cutting out in this wise from the intestinal tract almost the entire length of the large intestine. In five cases he had excellent results, in the sixth he used the Murphy button, which sloughed out, with consequent fatal peritonitis. Beck makes the following propositions based on the results of his experience, in formulating treatment for any given case of chronic colitis: (1) The cause of the colitis should be carefully determined in each instances and the treatment instituted accordingly. (2) If the colitis is the result of neighboring inflammatory processes, these should be attended to and if necessary by operative means. (3) When a carcinoma, tuberculosis or actinomycosis is the cause of the colitis, the local lesion should be attacked by radical or palliative operations (rececction, entero-anastomosis, colostomy). (4) Colitis found to be of different origin must be treated in a symptomatic dietetic manner. (5) Obstinate cases, which are not improved by these measures, should be subjected to the operation previously suggested. Beck claims that the large intestine is of comparatively little value in the human economy, being merely a remnant of a herbivorous type. By its tendency to the production of chronic inflammations and malignant growths, it furnishes an element of danger to the body, and may be readily cut out of the intestinal circuit without causing any disturbance in the economy of the system.

Postoperative Intestinal Obstruction.—Nothing is more discomforting to the patient nor disquieting to the surgeon than the failure of an operation, which has at the start seemed eminently successful. Charles H. Peck (*Annals of Surgery*, October, 1904) concludes that the possibility of postoperative obstruction should by no means be lost sight of after any intra-abdominal operation, but particularly so after such operations complicated by general or pelvic peritonitis. All raw surfaces should be covered with normal peritoneum, perhaps with cargile membrane, or by carefully arranged omentum. Small incisions and the gentlest manipulation are specifically indicated. The smallest possible drains should be used, if any; cigarette drains being vastly preferable to gauze. In the class of cases referred to, special care should be taken of the patient for the first few weeks of convalescence, particularly in the matter of regulating the bowels and the diet. Attacks of gaseous indigestion with colicky pains should be regarded with suspicion and treated with vigor. This treatment consists in giving enemata, gastric lavage, limited food, and posture. If, after a few hours' trial, palliative measures are unavailing, operation should be done at once, but it cannot be too positively stated that since these attacks of obstruction are usually partial in their incipiency, and are complicated either by late inflammatory swellings or by actual blocking of the lumen with coarse food, a great majority of them can be immediately and permanently relieved by palliative treatment.

Treatment of Hematemesis.—A great deal has recently been written on this subject which would justify one in believing that the sole prerequisite of the successful terminating of blood vomiting is gastro-enterostomy. F. G. Connell (*Annals of Surgery*, October, 1904) states that when such high authorities as Moynihan and Robson speak as they do in favor of gastro-enterostomy, it is but natural that the trend of surgical opinion is largely determined by their views. Moynihan says a gastro-enterostomy will prevent recurrence of the hemorrhage and lead to a rapid healing of the ulcer from which the blood comes. Munro has recently published the details of four cases of hemorrhage treated by gastro-enterostomy. All were followed by death. This fits in very pointedly with the belief of Moullin, who, in speaking of this operation for the relief of hemorrhage, says: "It is at best only a way of abating difficulties, which are better met directly, before they have attained dimensions which render this impracticable." Carcinoma, as a very prevalent, late occurring sequel is not the only contra-indication to this form of treatment. Many cases are recorded, including one by Connell, in which death was due to hemorrhage, which continued uninterruptedly after the operation. It hardly seems logical to believe that the mere putting of the stomach at rest to the degree of which gastro-enterostomy is capable, would suffice to stop hemorrhage from a good-sized eroded gastric artery. It follows, therefore, that in all cases, where it is practical so to do, radical treatment of the bleeding points should be attempted. Gastro-enterostomy is therefore indicated, first, if after a thorough search, the bleeding points cannot be found; second, when conditions are such as to make direct treatment impractical.

Sacculated Aneurism of the Aorta.—Since it seems quite possible that the Matas technic may before very long be called upon to invade the hitherto prohibited thoracic and abdominal aneurismal territories, all reports of cases treated by the older coagulation methods become doubly interesting. Hamilton A. Balance (*Lancet*, October 1, 1904) reports the case of a laborer, forty-four years old, for eighteen months had had a gnawing pain in the front of the chest on the right side. This pain was invariably worse after exertion and had at the time of operation become almost unendurable. Prolonged characteristic cough had practically in conjunction with the pain, obliged the man to give up work. Contrary to the usual belief, that syphilis is an almost invariable accompaniment of this form of aneurism, no such history could be obtained from the patient. On physical examination, the left pupil was larger than the right. The pulse was 64 and synchronous in both wrists. The chest bulged over the third and fourth right costal cartilages. Under medical treatment there was improvement. This, however, shortly disappeared, after the patient had begun to work. Two months later the tumor had almost doubled in size and the point of cardiac impulse was in the sixth space, half an inch outside the nipple line. The respirations were 30 and labored. In view of unendurable pain and of the unprecedented rapid growth of the aneurism, operation was finally decided upon. The skin was anesthetized with eucaine and a fine hollow needle, which just passed No. 9 silver wire, was introduced three inches into the fourth right intercostal space one inch from the border of the sternum. The wire was insulated by being passed through shellac. After the needle had entered the sac, the blood spurted over a foot high. Eight feet of wire were then passed into the sac. It had previously been wound in coiled form around a towel. It was shown experimentally that the wire would coil itself when unreeled from the towel through the needle. It took seven minutes to introduce the wire and there was irrgularity both in the rhythm and in the force of the pulse at the wrist, but the patient made no complaint. A constant current was passed into the sac for forty-five minutes, the end of the wire projecting being connected with the positive pole and an electrode being applied to the thigh. For the first fifteen minutes the current was five volts, 24 milliampères; for the next twenty minutes 10 volts, 42 milliampères. For the last ten minutes five volts, 28 milliampères. When the current was turned off, the end of the wire was pushed through into the sac, the needle withdrawn and the puncture sealed. For a quarter of an hour, the patient was comfortable, but after that he began to feel faint, to sweat profusely and to vomit. The pulse became feeble and irregular and fell from 96 to 50. At the end of the operation there was no diminution in the size of the pulsation of the aneurism. Recovery from this temporary dysgracia was complete and was apparently much aided by strychnine injections. For three weeks the pain remained about as before the operation. Likewise the swelling and tenderness about the sides of the puncture. At the end of the fourth week, however, there was marked diminution in size and morphine was discontinued, the patient being able to get up. Three months from the time of operation, the aneurism was pretty well solidified and all symptoms had abated. The wire in the sac showed very clearly under the X-ray. Three weeks later, however, dyspnea began to be sudden and severe. The respirations were 44. He expectorated blood-stained mucus and general edema developed. The aneurism at this time felt solid. He died on August 11, nearly ten months from the time of operation. The heart was greatly hypertrophied. The sacculated aneurism from the first part of the arch of the aorta was found. It was filled with a white clot in which the silver wire was coiled. Loops of wire also passed as far as the origin of the left common carotid and down to the bottom of the left ventricle. The wire had passed immediately after insertion into the ventricular cavity. The operation certainly prolonged life and prevented the patient from dying from rupture of the sac.

MEDICINE.

Fatal Poisoning Due to Absorption of Nitrobenzol.—A case of considerable interest is reported by W. J. Stone (*Jour. Am. Med. Ass'n*, Oct. 1, 1904) where this agent as an ingredient of shoe polish was absorbed through the skin. The man in question was suddenly seized with a fainting spell, which was succeeded by coma and collapse, with death following about four hours later. An autopsy showed acute desquamative nephritis and hepatitis evidently of a toxic nature. The feet showed marked discoloration. Subsequent inquiry developed the fact that the man had applied a large amount of a shoe polish to the uppers of his shoes and had worn them for several hours before death. Chemical examination of the shoes and the remains of the liquid, revealed the presence in both of large amounts of nitrobenzol. The case reiterates the danger of the promiscuous use of nitrobenzol by manufacturers as a solvent for the anilin dyes, and how more extensive poisoning is prevented among their workmen is a mystery. The case is also of interest as showing how absorption may readily take place through the skin and result in a fatal issue.

Tuberculosis of the Abdominal Lymph-nodes.—Having made an extensive study of this subject, C. F. Painter and W. G. Erving (*Am. Med.*, Sept. 24, 1904) state that the three chief sources of infection are direct extension from adjoining diseased tissues, infection from the blood stream, and infection through the lymphatics. The first is uncommon, the second is not infrequent, but the third is the usual mode. A lymph gland in which a tuberculous focus is present, remains always a source of danger to the rest of the body. The process may extend or remain localized, and it is to complications that in the latter case death is due. These may be, intestinal obstruction, peritonitis, or an outwardly progressing abscess. Among cases with spinal symptoms, mesenteric tuberculosis must be differentiated from Pott's disease, aneurism of the abdominal aorta, cancer, osteoarthritis, osteomyelitis, and other inflammatory diseases around the spine. The treatment of this condition may be considered under three heads, general, mechanical and operative. The first is the most important and includes all the factors which contribute toward the building up of the general system—outdoor life, freedom from labor, extra diet, tonics for the appetite. Even where the spine is not involved, the nearness of the spine to the diseased glands causes irritation and great benefit is secured from the wearing of jackets or spinal supports. Surgically, much the same rules hold good for the treatment of abscesses from broken-down lymph glands, as obtain in the treatment of abscesses from tuberculous bone

lesions. It is very important to prevent them from becoming secondarily infected, and therefore incision should be delayed as long as possible. Aspiration, when they are so situated that this may be done without danger to the viscera, is preferable to open incision. The latter, however, is only possible when strong presumptive evidence exists that the glands are isolated and small in number. But even where the abdomen is filled with a mass of glands, a simple celiotomy may be followed by a great improvement. The authors think that the prognosis is good as compared with that of vertebral tuberculosis in the same class of patients. The most serious features are due to the complications, but much can be done for the patient, according to the extent to which it is possible to provide efficient treatment. Patience and perseverence are also requisite. A series of eight cases is reported in detail.

Pathogenesis of Crisis in Pneumonia.—F. Tchistovitch (*Annales de l'Institut Pasteur,* No. 5) makes a study of the pathogenesis of crisis in fibrous pneumonia. In animals which have suffered from a pulmonary infection, and are on the road to recovery, a leucocytosis, and energetic destruction of diplococci by leucocytes takes place. On the other hand, in fatal infection, much more virulent diplococci are seen, the number of phagocytes in the blood diminishes and phagocytosis does not take place. Repeated experience indicates that crisis of pneumonia cannot be dissociated from the bacteriological property of the fluids of the organism. The blood of a patient suffering from pneumonia during or after the crisis, would not be bactericidal to diplococci of the same disease. Tchistovitch concludes that the blood of a convalescencing patient of pneumonia has not the energetic antitoxic property sometimes supposed. One must admit that phagocytosis is the chief factor in cure of pneumonia. The quantity of alexins in the blood increases during the course of a pneumonia, and reaches its maximum at the moment in which the disease commences the stage of resolution. After this the alexins diminish more or less rapidly. In grave cases with fatal outcome the quantity of alexins does not stand in relation with the total number of leucocytes. In 1887 it was demonstrated that the blood of an acute case of pneumonia, injected under the skin of an animal caused a rise of temperature, but serum from a convalescing case of pneumonia produces no effect.

Cytology of Hydrocele.—In seven cases of chronic hydrocele, Julliard demonstrated a variable number of endothelial cells. Lymphocytes and red corpuscles were sometimes found, but referred to the traumatism of puncture. Liquid from acute gonorrheal hydrocele showed a preponderance of polynuclear elements, but in syphilitic hydrocele, besides endothelial cells, were found lymphocytes, eosinophiles, and polynuclears. Oscar Marchetti (*Gazz. degli Osped.* August 7, 1904) reports observations on 30 cases. In simple hydrocele there were few cellular elements. Usually some epithelial cells were present, and lymphocytes. In hydrocele secondary to tuberculosis he finds a high percentage of epithelial cells—25 to 52 per cent., and 25 per cent. of lymphocytes and eosinophiles or polynuclear cells in smaller amount.

Spontaneous Gangrene.—An accompaniment of hysteria—hysterical blindness and paralysis—is rare, but spontaneous gangrene of the skin as an accompaniment to this series of nervous symptoms is very much less frequently seen. W. A. Mearns (*Lancet,* September 17, 1904) records the history of a patient, aged twenty-four years, who first consulted him for a skin trouble on the lower part of her neck. She was a frail woman and was known to have hysterical tendencies. She had always been irregular in her menstruation, and presented the characteristics which are usually called forth by profound anemia. The appearance of the lesion was in itself not significant. It was simply a dark-red area the size of a ten-cent piece just above the middle third of the right clavicle. The subjective disturbances which had been observed at the time of its appearance were simply a burning sensation over the region. A tentative diagnosis of herpes was made and treatment accordingly instituted. The author did not see her again for a week, at the expiration of which time he was called, her neck having become very much worse. It was already gangrenous, and on raising the surface pus could be detected beneath it. Already a second area had developed, somewhat below the primary one, but this had not yet gone on to degeneration. The pain was intense, and morphine had to be administered. Hot boric acid fomentations were applied to the sloughing area, after which the necrosed tissue separated. By the next day a similar condition was to be observed in the area secondarily involved. The dead parts were not unlike those which would be seen after the application of pure carbolic. Subsequently the lesions extended progressively down to the right breast; in each case the size was about equal to that of the first one, and the cycle traversed was the same. In all seven areas were involved. The area by this time was so large that skin grafting was resorted to, but the grafts twice refused to heal. Throughout the temperature was slightly above normal, registering usually about 99° F. On two occasions, however, extraordinary rises took place without any apparent cause, once to 105° F. and the second time to 110° F. Finally, after nearly five months in the hospital, the patient was discharged with the part healed, but with very extensive and disfiguring cicatrices on the neck and breast.

Local Use of Quinine in Hay Fever.—A form of treatment which has been used with success is recommended by H. D. Fulton (*Jour. Am. Med. Ass'n,* July 30, 1904). It consists of the employment of a saturated solution of quinine sulphate, in sterile water, as a nasal spray, and the application to the mucous membrane of the nares of an ointment consisting of quinine and simple vaselin in the proportion of thirty grains to the ounce the applications being made every four or six hours. Spraying the nares will at once stop all symptoms of coryza, but the effect will soon disappear unless followed by the thorough application of the ointment. Where the bitter taste of the quinine is objected to, euquinine is an equally efficacious substitute.

A New Hypnotic.—The amides of the lower fatty acids have a distinct narcotic action which is enhanced by adding bromine and ethyl radicals to the molecule. G. Fuchs and E. Schultze (*Münch. med. Woch.,* June 21, 1904) have manufactured bromdiethylacetamid synthetically and placed it upon the market under the trade name neuronal. It seems to exceed all other hypnotics in efficacy and is safe and not followed by untoward after-effects. The average dose is one gram, to be followed by hot liquids. The drug also acts as a sedative and may be of some value in epilepsy. Like most of these best yet hypnotics it will require much experience to determine its true position.

SATURDAY, NOVEMBER 5, 1904.

THE THIRD ANNUAL REPORT OF THE HARVARD CANCER COMMISSION.

Four contributions to the discussion as to the etiology of cancer are presented in the report of the Harvard Cancer Committee made this week before the Boston Society of Medical Sciences. As was the case with the report made a year ago, the work has been largely destructive without obvious constructive facts to replace those opposed,—a condition of things none too satisfactory, but which yet must be gratefully accepted until a better knowledge of the chemistry of tissue metabolism shall allow of positive advance. The work accomplished tends, as heretofore, toward a demolition of the parasitic hypotheses.

The elaborate and painstaking researches of R. B. Greenough and of E. H. Nichols seem to be the most important of the year's work reported. Dr. Greenough has continued his study of the cell-inclusions of cancer. These bodies, supposed by some to be protozoan in nature, are found to be in all probability only vacuoles formed within gland cells. Reporting nearly five hundred examinations made by four observers on various sorts of cancerous growths, on sarcomata, and on different sorts of tissue, it was found that these rounded objects, the so-called Plimmer's bodies, are much more common in gland cells than elsewhere, never occurring for example, in epitheliomata, and never, with a single exception, "proving the rule," in sarcomata. Numerous lantern slides made from drawings were adduced to prove that these cell inclusions are secretory in nature, formed by the aggregation of secreted ganules which collect in masses, degenerate, and lead to the formation of vacuoles in the cytoplasm. These vacuoles almost always appear in the body of the cell between the nucleus and the duct-lumen,—the location where secretory products are most apt to be found. The strongly staining solid masses in the interior of these vacuoles remains to be explained somewhat, however, as does the peculiar structure of the periphery of the bodies.

Of fifty-four implantations of tissues made in guinea-pigs and in rabbits by Dr. Nichols none led to the production of cancer, unless the tissue transplanted was cancerous, in which case the form of cancer reproduced was always identical with that of the carcinoma from which the implanted bit of tissue was taken. All sorts of animals, save the very simplest, are now known to have cancers, but the transference from one animal species to another has never been accomplished, and only in rats and mice has the infection of one individual by another by transplantation been proven to be possible. The statistics do not tend to prove a relative increase of cancer, nor its occurrence in localities or certain houses beyond what chance will quite account for. This result corroborates that of the English cancer commission reported last spring, and in general the trend of the work is the same, namely, toward the non-infectiousness and the metabolic nature of this deadly scourge.

W. C. Howe and Robert Vose presented a careful and instructive summary of the observations made at the Massachusetts General Hospital on the effects of Roentgen rays on cancers, especially on those of a superficial location. This paper is distinctly discouraging as concerns the curative effects of this agent on malignant growths of a cancerous nature. In a fair proportion of cases epitheliomata have been apparently cured, but more often than not the effect has been by what is practically cauterization, by a slow burning away in toto of the diseased area; and for this purpose the knife is both more prompt and more certain. In the cases treated up to the limit of commencing tissue-destruction

the therapeutic effect was usually found to be only palliative, recurrence occurring as it would after incomplete removal by the scalpel. Deeply seated cancers appear to be wholly beyond the influence of the rays.

Dr. F. B. Mallory, the recent describer of the protozoan of scarlatina, offered a contribution to the classification of tumors based on the long fibrils found to connect three sorts of cells, namely, neuroglia, unstriated muscles and connective-tissue cells. This report was only preliminary, and in its matter too complex for report editorially.

Altogether the third year's work on cancer in the Harvard Medical School has been negatively productive, but tends, on the whole, to make even yet more obscure the solution to this one of the deepest as it is one of the most vital problems of medicine. It is to be hoped that the further work undertaken, perhaps not by the pathologists, but by the embryologists and physiological chemists, will contribute more than a bar to progress in one direction, namely, some help along the direct road to the goal of the truth, to the vast benefit of suffering man and brute.

SERUM DIAGNOSIS OF CARCINOMA OF THE STOMACH.

Until quite recently it has been tacitly assumed that during the process of precipitation of antibodies the immune serum represented the active, and the immunizing solution the passive reagent. In other words, it was thought that the precipitate which results upon the addition of immune serum to a solution of the immunizing substance was formed at the expense of the latter.

Through the researches of Moll,[1] and, more recently, those of Maragliano,[2] this view has been disproven, and it has been demonstrated quite conclusively that the reaction follows exactly the opposite course. During the process of precipitation accordingly the immune serum plays the passive and the immunizing solution the active rôle.

This fact is of fundamental importance in the application of the reaction in the serum diagnosis of malignant disease, which has of late been repeatedly essayed. Engel and Kullmann, whose work antedates the observations of Moll and Maragliano, and was based upon the older conception of the course of precipitation, thus only arrived at negative results. They found that rabbits that had been immunized with blood-serum of carcinomatous patients or with extracts of carcinomatous tissue, furnished a serum which yielded a precipitate with all albuminous solutions, no matter whether these were derived from carcinomatous or non-carcinomatous individuals. Considering the nature of the immunizing agent, this result was of course to be anticipated, even though the exact cause of the precipitation reaction was not then understood. But granted that the principle of the method were applicable for diagnostic purposes, it would have been necessary, in the light of Moll's and Maragliano's researches, to first precipitate the immune serum with dilute blood-serum from non-carcinomatous individuals, so as to remove all precipitations which were referable to the human serum as such. If then the immune serum were to furnish a precipitate with carcinomatous blood, the reaction might possibly be regarded as specific for carcinoma.

Satisfactory researches in this direction are as yet wanting. Analogous experiments, however, have recently been performed by Maragliano, in which the serum secreted from ulcerating carcinomata of the stomach was used for immunizing purposes. The technical details are the following: A patient with carcinoma of the stomach is placed upon a special diet, as suggested by Salomon (*Deutsche medicinische Wochenschrift*, 1903, No. 31). The stomach is then washed out before retiring. The next morning half a glassful of physiological salt solution is given and the stomach contents procured five minutes later. If this solution contains albumin (as shown by the nitric acid test) it is suitable for examination. To this end rabbits are used and injected twice a week with from 10 to 15 c.c. of the washings, ten or eleven injections being made in all. The resulting immune serum is then treated with small amounts of a 1:50 solution of human blood. A slight precipitate usually develops, which, after standing for several hours in the incubator, is removed by centrifugation. The clear supernatant fluid is drawn off and examined once more with a little normal blood solution, so as to insure the complete absence of normal blood precipitations. Finally, the immune, carcinoma-rabbit blood-serum is treated with the stomach washings to be examined, when, according to Maragliano, a precipitate is formed, if the solution under examination comes from a carcino-

2 Maragliano, D. Berlin. klin. Woch., 1904, No. 27.

matous stomach. It does not develop, on the other hand, if the stomach contents are not of a carcinomatous origin.

A detailed account of Maragliano's work has thus far not appeared, but it is manifest from the brief survey which has here been given that we may soon be in possession of a method of diagnosis of gastric carcinoma which will in a sense be specific. Whether or not it will render possible an earlier diagnosis of the disease than can be achieved with the methods which have heretofore been at our disposal, time alone can tell. If so, it will represent one of the most valuable results of modern immunity research.

PNEUMONIA ONCE MORE.

We are entering upon the season of the year when the curve of the death-rate from pneumonia begins one of its sharpest annual inclines and reaches one of its two maxima. There is no doubt that the disease has become one of the most serious that afflicts mankind, and of late years the statistics of its mortality dinned into our ears by many writers, have brought out this fact with incontrovertible certainty. There has even come to be a very general impression that the disease is much more frequent and much more fatal in very recent years than ever before in medical history, and some writers insist that the story of its increasing deadliness can be read very plainly in the municipal statistics of the various boards of health, especially in large cities throughout the United States, and that even since 1900 there is an alarmingly formidable advance easily traceable both in its incidence and fatality.

At the beginning of October the Chicago Board of Health, in its weekly report on the state of Chicago's health, said:

"Pneumonia caused 54.4 per cent. more deaths in 1900 than all the other contagious and infectious diseases combined — including cerebro-spinal fever, erysipelas, diphtheria, influenza, malarial fevers, measles, mumps, puerperal fever, scarlet fever, smallpox, typhoid fever and whooping-cough, the total of which was 2,196. In 1903 it caused 87.7 per cent. more than these diseases combined, the total of which was 2,466 in 1903."

This has its very serious aspect, and yet we doubt if the condition of affairs is quite as appalling as statistics would seem to indicate. It was an irate medical man who, like David in his wrath, said, not that all men are liars, nor that all statistics were lies, but that there were three kinds of lies: plain, ordinary every-day lies, blank lies, and statistics. As a clever medical man has recently put it, figures do not lie, but lies may figure in statistics. There seems no doubt that an analysis of the statistics would greatly reduce the apparent increase in the death-rate from pneumonia. In recent years physicians, especially in large cities, have become much more exact in their declarations in death certificates as to the cause of the deaths of patients. This is especially true for the very young and the old.

In the not very recent past old age figured as a prominent cause of death in statistics, while now it is the terminal pneumonia that the more accurate diagnostician very properly sets down as the cause. In children, pneumonia was not set down as the cause of death in most of the children's diseases, if it came only as the terminal complication of them. This was true also with regard to consumption before so much attention was devoted to it. It is not infrequent now to find that a physician, who has been treating a patient for tuberculosis of the lungs for several years, will state on the death certificate that the direct cause of death was pneumonia, though the indirect cause may be set down as tuberculosis. The physician is usually right in this, for in young persons particularly it is an acute exacerbation of their pneumonic condition that often causes death. Perhaps many of us are also influenced by the fact that a great many of the middle class in our large cities are insured, and their friends would distinctly prefer that the word pulmonary tuberculosis should not be put on the death certificate, and we yield the point and stretch our consciences as far as the word pneumonia.

While the municipal statistics of many large cities would seem to indicate a very great increase in mortality from pneumonia, physicians in active practice for many years insist that this increase has not been brought home to them. Of course this is a vague objection to be urged against exact and carefully collected and scientifically collated figures. At the last meeting of the American Medical Association, however, some forcible opinions of well-known clinicians with regard to this matter were expressed when the question of pneumonia was under discussion. Among conservative Eastern physicians at least, there seemed a consensus of opinion that the scare with regard to the increase of pneumonia was being overdone.

There is, of course, one very decided objection

to the publication of such statistics until they have been absolutely determined to be true, and so are likely to do good rather than harm. Newspapers get hold of these startling figures and use them as sensational scare heads. The result is that many a man, when told that he has pneumonia, practically gives up all hope of recovery at once. In respiratory diseases, more than any other form of affection, courage and confidence on the part of the patient is of prime necessity for hopeful therapeutics and for a favorable prognosis. The widespread publication of the apparently great increase of fatality of pneumonia in recent years is likely to add seriously to the number of fatal cases.

While, then, the new "Captain of the men of death," to quote Prof. Osler's expressive phrase, deserves the most earnest attention in the hope that some method of hindering his fearful ravages may be found, it seems extremely inadvisable to insist on calling public attention to the matter so vividly. Physicians, sanitarians, municipal health authorities and those engaged in questions of hygiene, now know of the fatality as exhibited in statistics, and we may hope for further confirmation of the figures, but until certain factors that enter into the problem have been eliminated by time and patient research, we cannot know the absolute truth in the matter, and until then the sensational publication of the apparent increase seems utterly inadvisable.

ECHOES AND NEWS.

NEW YORK.

Removal of Dr. W. E. Bullard.—Dr. William E. Bullard, formerly of this city, and for the past five winters the Resident Physician at the Colonial Hotel, Nassau, Bahamas, has been offered and has accepted a similar position at Palm Beach, Florida, where he will be after December 23.

City's Lowest Death Rate.—Dr. Thomas F. Darlington, Commissioner of the Health Department, announced at the board meeting last week, that the death rate for the week ending last Saturday was the lowest ever recorded in the history of Greater New York. It was 14.46. The number of deaths was 678, and the basis of estimated population 3,570,012. Dr. Darlington said that, in response to petitions by the hospital patients on North Brother Island, he will make an effort to have a chapel for their use built there.

Dr. Dold Goes to Falkirk.—Dr. Wm. Elliott Dold begs to announce to the medical profession, that he has accepted the position of medical superintendent of Falkirk, Central Valley, Orange County, N. Y.

Honors at Columbia.—Among those of the medical profession to receive honors from Columbia, at her one hundred and fiftieth anniversary celebration, were, Drs. William H. Welch, Andrew James McCosh, Walter B. James, Francis Delafield, Edward G. Janeway, John G. Curtis, William M. Polk, who received the honorary degree of Doctor of Laws, and Drs. M. Allen Starr, L. Emmett Holt, W. S. Halstead and George S. Huntington, who received the degree of D.Sc.

Wood Alcohol Finds.—The Board of Health has found some wood alcohol in whisky, now that the horse has been stolen. They have recently had arrested a saloon-keeper in whose whisky wood alcohol was present, and the trial is now on.

Banquet to Sir Felix Semon.—More than one hundred throat specialists assembled in Delmonico's last Tuesday, at a banquet in honor of Sir Felix Semon, physician extraordinary to King Edward VII, who was a guest of the section of laryngology of the Academy of Medicine. Sir Felix has just returned from a month's hunting in Canada, after delivering an address before the Congress of Arts and Sciences at the World's Fair, in St. Louis. The banquet was presided over by Dr. Harmon Smith, the special committee in charge of the entertainment being composed of Dr. J. W. Gleitsman, Professor W. K. Simpson, Dr. J. E. Newcomb, Dr. Walter E. Chappell and Dr. Emil Mayer. Prominent throat specialists were present from Baltimore, Washington, Philadelphia, Harrisburg, Boston, Springfield, Troy, Utica, Albany and Buffalo. Toasts were responded to by Dr. Harmon Smith, Sir Felix Semon, Andrew H. Smith, Professor George M. Lefferts, Dr. C. C. Rice and others. On Wednesday afternoon Dr. and Mrs. Edward B. Dench gave a luncheon in honor of Sir Felix and Lady Semon, and the same night Sir Felix addressed the profession in the hall of the Academy of Medicine on "Malignant Diseases of the Larynx." Thursday afternoon he delivered a lecture to the Long Island College, and the same evening attended a banquet in his honor given by Dr. George Lefferts. This evening Dr. and Mrs. Emil Mayer will give a dinner in honor of Sir Felix and Lady Semon.

Manhattan Dermatological Society.—Regular monthly meeting of this Society, held on Friday, October 7, 1904, at the residence of Dr. W. S. Gottheil, Dr. I. P. Oberndorfer presiding. The following cases were presented: Dr. J. Sobel presented a female adult patient showing squamous lesions along the hair line (forehead) and postauricular regions, which looked typical of eczema seborrheicum, on the body, arms and legs, dry, white glistening squamous lesions, typical of psoriasis. Not guided by the lesions on the body Dr. Sobel would call this case one of seborrheic eczema, but the typical psoriatic lesions on the body justify the question, Have we here a double eruption to deal with, or might not the case be properly classified under the title of eczema seborrheicum psoriasiforme? Dr. Ochs accepts the latter diagnosis. Dr. Abrahams does not hesitate to say that he recognizes two distinct lesions, psoriasis and eczema seborrheicum. Dr. Gottheil spoke of the differential diagnosis and the difficulty of recognizing clinically, at times, the difference between seborrheic eczema, psoriasis, and eczema seborrheicum psoriasiforme. Dr. Bleiman said that eczema, seborrhea, and psoriasis were closely related, although he thought they were two distinct diseases; either condition may assume the characters of the other, in the course of their development or the result of treatment. Dr. Oberndorfer claims there is such a disease as eczema seborrheicum psoriasiforme. The present case he called a psoriasis with marked seborrheic element.

Dr. B. F. Ochs presented two cases: (1) Leucoderma, in a female patient eighteen years old; condition began when three years old; the patches are symmetrical and seen on face, arms, back, pubic and crural regions; patient is a blonde. (2) A male adult, thirty-four years old; patient states he had a sore on penis ten years ago. Seven months ago noticed a small white patch (resembling a mucous patch) on left dorsum of tongue; antiluetic treatment gave negative results; recently the patch became a distinct ulceration and is now painful and fissured. Large dose of KI internally, and Hg hypodermatically produce no effect. Dr. Oberndorfer looks upon it as a syphiloma; he thought the KI and Hg should be pushed and if after a fair trial with heroic doses no effects were discernible, he would entertain a possible diagnosis of epithelioma. Drs. Gottheil, Sobel and Abrahams agree with the latter speaker; the history was misleading and entitled patient to a thorough course of antisyphilitic treatment, before radical measures were entertained.

Dr. R. Abrahams presented a woman with ulcerations on lower legs, resembling syphilitic lesions; other lesions on the elbows assumed the type of tuberculous ulcers; under KI and Hg, the latter got well but the former are getting worse. The skin over upper third of tibia shows old scars and the tibia shows periosteal nodes. Dr. Abrahams believes he has a double infection to deal with. The majority of the members regard the case as specific.

Dr. W. S. Gottheil showed the following cases: (1) Lupus vulgaris of the face, nose, ears and neck, in a male adult, of sixteen years' duration. Under X-ray treatment for three months gave negative results. The nitrate of silver stick accomplished almost a complete cure; the remaining scar tissue produces traction on lower eyelids and the ears. (2) Leucoderma, in an old man (presented at a previous meeting). (3) Lichen planus ruber in a young man of twenty-one years; eruption began three months ago and is now general all over the body; mucous membranes also involved. (4) Deep gumma involving the muscular tissues of the knee in a young male adult. (5) Male, aged thirty-five years; skin always clear up to three months ago, then noticed small rounded tumors along the calves and later involving regions of the wrists and elbows. Other swellings gradually developed; patient is losing flesh and strength rapidly and looks cachectic; presented as a case of multiple sarcoma of skin. (6) Adult, female; general eruption on body, consisting of macules and papules; mucous membranes clear; eruption itching; patient states that three years ago she had an abscess of the breast after childbirth which took a long time to heal; three months ago the same breast had a "sore," which likewise took some time to heal; the latter was of a different nature and is supposed to have been chancre (?). Dr. Gottheil does not hesitate to call the macular eruption a secondary manifestation of syphilis and the nodular eruption he regards as urticaria. Dr. Abrahams said the case was one of erythema multiforme. Dr. Cocks thought the patient had syphilis; the present lesion being a late secondary eruption. Dr. Ochs regarded it as syphilitic eruption and also pityriasis rosea. Dr. Kinch called it a squamous syphilide and an urticaria. The second breast sore spoken of by patient was possibly the initial lesion. Drs. Sohel, Bleiman and Oberndorfer regard the macular eruption as pityriasis rosea and the papular eruption as possibly syphilis. Dr. Gottheil presented photographs of an interesting case of pemphigus foliaceus and a case of Addison's disease.

PHILADELPHIA.

Health of the City.—Epidemics of throat diseases are threatening the city. Diphtheria and tonsillitis are prevalent to an unusual degree, the former especially. Last week there were 18 deaths due to diphtheria and several schools were closed on account of the disease.

Private Hospitals to be Under Supervision.—In the future the seven private maternity hospitals holding license from the Bureau of Health will be inspected weekly by inspectors attached to the Bureau. Every room and each patient will be visited. This action is one of the results of the recent exposures of malpractice by the coroner's office. Heretofore the inspection has been done in a spasmodic manner only.

University Laboratories Completed.—The new medical laboratories of the University of Pennsylvania are now ready for use throughout. The last of the equipment was made possible by a gift of $7,000 from Provost Harrison.

Railroads and Health Boards.—Dr. Benjamin Lee, Secretary of the State Board of Health, says that if all persons having control of great interests and employing many men were as ready to enforce sanitary laws as are the railroad companies, the work of the Board would be greatly simplified. The managers of railroads are ready to accept suggestions regarding precautions against contagious diseases "following out its suggestion that all matters of sanitation connected with railroads, such as care of buildings, heating, ventilation, lighting, cleansing and disinfecting cars and selection of water supplies, should be under the charge of a medical officer trained in chemistry, bacteriology and general sanitation and hygiene, the State Board has appointed the physician-in-chief of each of the great trunk systems running through this State as a special inspector of the Board, having first assured itself of his thorough competency as a sanitary officer. In addition to this, the State Board has named the majority of the corps of medical assistants as deputy inspectors for their several roads."

The Absorption of Fibrin.—At the meeting of the Pathological Society of Philadelphia on October 27, Dr. Joseph McFarland detailed some experiments made to determine if a solvent for fibrin could be produced by the injection into animals of that material. A large quantity of fibrin was obtained from horses that were bled for antitoxin purposes, washed for forty-eight hours in running water, dried, powdered and suspended in fluid for injection. Rats and guinea-pigs were injected but nearly all died of infection. At the suggestion of Metschnikoff he then employed dogs, with much greater success, so far as death was concerned. Experiments lasting over several months, however, failed to produce in the serum of the injected animals any substance that was solvent for fibrin. Dr. McFarland concludes that no solvent of this type can be produced in animal serum by injecting fibrin.

Contributions to Science of Professor Leidy.—A recent publication of the Smithsonian Institution is "Researches in Helminthology and Parasitology" by Joseph Leidy, M.D., LL.D. The various papers of Professor Leidy on this subject make a book of 248 pages. To the collection it added a bibliography

of his contributions to science consisting of 559 titles. The series has been edited by Joseph Leidy, Jr., M.D., and forms a most valuable collection.

Alvarenga Prize of the College of Physicians of Philadelphia.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $180, will be made on July 14, 1905, provided that an essay deemed by the committee of award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the Secretary of the College on or before May 1, 1905. Each essay must be sent without signature, but must be plainly marked with a motto and must be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award. The Alvarenga prize for 1904 was not awarded, no essay of sufficient merit, in the judgment of the committee, having been submitted in competition.

CHICAGO.

Memorial Services in Honor of Nathan Smith Davis.—Tribute to the achievements and character of the late Dr. N. S. Davis, head of the Northwestern University Medical School at one time, and for years the leader of medical thought in Chicago, was paid in memorial services held under the auspices of the Chicago Medical Society, in Powers' Theater, Sunday afternoon, October 23. Dr. John B. Murphy, president of the Chicago Medical Society, presided. The church, represented by Bishop John Lancaster Spalding, of Peoria, Illinois, and Bishop S. M. Merrill, of Chicago, joined with the eminent physician's colleagues in eulogy. The principal addresses were delivered by Bishop Spalding and Bishop Merrill. At the memorial services a letter was read from Mr. Henry G. Foreman, President of the Park Commissioners of Chicago, in which it was announced that, on account "of Dr. Davis' services to the City of Chicago, and because of the high esteem in which he was held by the citizens," the South Park Commissioners had named one of the new parks "Davis Square," in honor of Dr. Davis. It is bounded by Forty-fourth Street, Forty-fifth Street, Marshfield and Hermitage avenues, contains a little over ten acres, and in the park field house a tablet will be placed in memory of Dr. Davis.

Appointment of Dr. Türck.—In November, Dr. Raymond Custer Türck, demonstrator of anatomy in the Post-Graduate Medical School, will go to Alma, Mich., as medical director and business manager of the Alma Springs Sanitarium.

Chicago Gynecological Society.—At the annual meeting, recently held, the following officers were elected: President, Dr. J. Clarence Webster; First Vice-President, Dr. Frank T. Andrews; Second Vice-President, Dr. Henry F. Lewis; Secretary, Dr. Palmer Findley; Editor, Dr. Rudolph W. Holmes; Treasurer, Dr. Charles B. Reed; Pathologist, Dr. Gustav Kolischer; and Councillor, Dr. Emil Ries. The report of the Secretary showed that the average attendance had almost trebled during the year.

Credit to be Given Practitioners in Examinations for Years of Practice.—The Illinois State Board of Health, at a meeting held in this city October 22, adopted the following resolution, which was presented by Dr. J. A. Egan, Secretary of the Board: *Resolved*, That the rules of the State Board of Health, adopted July 11, 1899, regarding the character of examinations, are hereby amended as follows: On and after January 1, 1905, the Illinois State Board of Health will accept as an equivalent of a part of the examination required satisfactory evidence of five or more years of reputable practice of medicine and surgery since graduation, and will allow a credit of 5 per cent. on the required average of seventy-five per cent. for each period of five years of such practice on the part of a candidate for a certificate.

Chicago Pediatric Society.—At the October meeting of this society summer diarrheas of children was the topic for discussion. Dr. A. C. Cotton presented a review of the recent literature on the subject, and, among other things, stated that dysentery had been known as far back as the fifth century. The characteristic lesions and repair had been described, showing that autopsies had been made. Endemic, epidemic, and sporadic dysentery had been reported. Almost nothing except the geographical distribution was added until the discovery of the *Amœba coli* or *dysenteriæ* in 1875 by Losch. In an epidemic in Japan, in 1898, in which there were 1,900,000 cases, and a mortality of 25 per cent., the Shiga bacillus was discovered by a Japanese physician. Discoveries followed in other countries. The 1903 report of the Rockefeller Institute for Medical Research in New York being the most available and comprehensive work on the subject just at present, the author extracted from it many points of interest.

Dr. George H. Weaver, bacteriologist of Rush Medical College, spoke on some bacteriological observations in connection with summer diarrhea. He presented charts showing results of cultural work. He said that in 102 cases taken from the sanitarium at Lincoln Park during the last summer 76 were negative and 27 yielded the dysentery bacillus. He touched on the history of the dysentery bacillus and the difficulties in the attempt to differentiate the organism. As the result of experiments, the tendency is now to group instead of individualize—for instance, one group has a certain action on dextrose only—another on lactose only, etc. Flexner founds his classification on the fermentation of dextrin; others have other bases of classification. There are two general groups, the acid or mannite, and the non-acid. Shiga is used as a broad term to cover all the non-acid group. In Constantinople a bacillus was isolated, which produced acid in milk and the characteristic dysentery lesions in cats, but seemed more like colon bacillus. Other investigators have found the characteristic lesion of dysentery caused by different organisms, so that the opinion now in general is that dysentery is a clinical picture and not an entity. Specific agglutination also is losing a good deal of its value. The Widal test has not so special a significance as it did have. The reaction is not specific in dysentery, either, as it gives the reaction fully as well in typhoid fever as in dysentery. Duval and Bassett record agglutination in 42 out of 53 cases of dysentery, and Wolfstein 39 out of 140, but the agglutination was not present until after the antidysenteric serum was administered. Flexner found it in the Rockefeller Institute in 270 out of 412 cases. Antidysenteric serum was used there, but it is not known whether it was used in all these cases. Dunn, in Rotch's clinic, found it in 10 out of 61 cases. They threw out all cases not agglutinated by the antidysenteric serum. If the dysenteric condition does not exist, it is wrong to use the serum. If not needed, it would be a disturbing element and might do harm. In

the 76 negative cases, 27,050 colonies were made. Of the 27 cases showing the dysentery bacillus, 17 gave the bacillus Y. This distinction has not been made in other reports. The true Shiga bacillus was not found at all. The organism produces different action on glucose, maltose and dextrose, and on different culture media, so that its isolation may depend upon conditions. The question is, Which are and which are not dysenteric bacilli? So unlimited numbers of cultures must be examined. Duval examined the milk stools of healthy babies, and found the dysentery bacillus in two cases, both culturally and by agglutination. In a large part of the cases of summer diarrhea, the dysentery bacillus was not found, or only in small numbers. Probably the ordinary cases of summer diarrhea are not due to the dysentery bacillus, but to various bacilli. Epidemics may be due to the dysentery bacillus. In the controls the agglutination occurred in a dilution of 1 to 400 sometimes, but usually in 1 to 200. Blood serum from scarlet fever and convalescing typhoid fever patients both agglutinated in the same dilution as blood serum from the dysentery patient, showing that dysentery is not a specific infection.

Dr. May Michael read a clinical report of the 102 cases examined by Dr. Weaver, giving the age, diet, character of stools, range of temperature, complications and termination of the cases. Mucus and blood were found in all but two of the cases in which the dysentery bacillus was found. The bacillus was not found in any case under six months of age, the largest number being between one and two years of age. The most of the cases were artificially fed. Four in the 27 cases in which the dysentery bacillus were found died, but recovery was the rule. Rickets, pneumonia, bronchitis, marasmus, whooping-cough were the most common complications, but many of the cases were in good physical condition at the outset of the diarrhea. The antidysenteric serum was used in one case, with no result.

Dr. John C. Cook reported 18 cases, in none of which was he able to isolate the dysentery bacilus, and none gave a clinical picture of dysentery. He found in cultures from the throat or stools one or more of the following organisms: Diplococcus, lactic acid pneumococcus, typhoid, sarcina, yeast, a short, thick bacillus, and a long, slender bacillus. The clinical symptoms were varied. There were complications of marasmus, brought on by improper feeding at home, and especially pneumonia. Five died, two of pneumonia, one of typhoid fever, in which the Widal test was positive. Antidysenteric serum was used in one case without result. One case recovered in which the organisms contained in its stool injected into a guinea pig caused its death. Two cases, one the typhoid fever case, and another reported by the nurse as having had two severe hemorrhages from the bowels, showed in culture a pigmenting organism staining the media a red color. The suggestion was advanced that the color in the stool might be due to the action of this organism on the mucus. The stool did not color water as blood does. The bacteriologists working for Dr. Cook, Mr. Gill and Mr. Bain, of Northwestern University Medical School, hoped to name this organism some day. One case that died at post-mortem showed bronchopneumonia, that could not by physical examination, pulse, temperature or respirations, be determined during life. Most of the deaths were due either to pneumonia or toxemia resulting from improper feeding.

Dr. William J. Butler reported ten cases from Cook County Hospital, in all of which the antidysenteric serum was used, without results in any case. All these cases had blood and mucus in the stools, but in only two was the dysentery bacillus found. Clinically, the cases varied, but the stool was usually green, the temperature high, and the pulse and respirations rapid. One case improved while using the serum, but the improvement was thought to be due to the use of calomel and whey rather than to serum. One case on milk and barley water diet showed no change in temperature, pulse or stool for five days under the serum treatment, but improved in every respect when diet was changed to albumin water.

GENERAL.

Another Yellow Fever Expedition.—The Liverpool School of Tropical Medicine intends shortly to send out a second yellow fever expedition to the Amazon, in view of the necessity of investigating still further a malady which continues to claim so many victims. It will be remembered that the late Dr. Walter Myers was selected by the school, together with Dr. Herbert Durham, to undertake an expedition to Para to investigate the fatal disease only a few years ago. Unfortunately, both members of the expedition were attacked by the malady and Dr. Myers succumbed. The expedition will probably start at the end of the year.

Medical Socialism.—The canton of Zürich has carried the activity of the State to a remarkable length. It has decided to levy an annual poll-tax of 86 cents, to be called the Zürich Medical Tax. It will produce $100,000 a year, sufficient to maintain forty or fifty qualified doctors; and in return for paying the tax any inhabitant will be entitled to call in one of these doctors at any moment to claim medical attendance free of charge all the year round. There is no great fear that the precendent will be followed in our own country, writes a correspondent of the *Pall Mall Gazette* of London, until the Zürich experiment has had plenty of time to be tried. The medical profession could, no doubt, be relied upon to oppose any such scheme. It is appalling to think of the burden that is likely to be thrown upon those unhappy forty or fifty Swiss doctors, if the people of Zürich are at all like our own. It is not only among rich people who have little else to do but to imagine themselves dying that panic-stricken desires for the doctor, on the occasion of the slightest ache or discomfort, are common; the domestic servant class are equally prone to this weakness. Unless the State doctors adopt a bearish repulsiveness of manner in self-defence, they will have work enough.

Japan Hospital Service.—The Army General Staff, writes the *Sun*, is to be commended for its decision to dispatch surgeons to the regular army to observe the operations of the field hospital service of the armies now engaged in Manchuria. The particular point open to criticism in this decision lies in the purpose to send only one representative to each army. It would be better to send two, or even more, with which we thoroughly agree. It is remarkable that within so short a time after the close of wars in which such nations as England and the the United States have been engaged, it should be possible for the War Department of this country to state officially "that it has become evident to the General Staff that there has been almost a revolution in field hospital methods as a result of the war as far as it has gone." "We are somewhat disposed to doubt whether this is an exact statement of the case. It seems far more probable, in the case of Japan at least, that the comparative freedom of Japanese camps and moving armies from those epidemics which are the usual attendants of military bodies, and the success of field

surgery in the treatment of wounded men, is due far more to Japanese prevision and preparation than to lessons learned since the outbreak of hostilities. While the treatment of wounds in field hospitals is of unquestionable importance, it is of far less importance than is the prevention and cure of diseases in camp. This is established by the fact that from April until September 30, 1898, the records of the United States Army show 345 deaths in action or from wounds received in action and 2,565 deaths from causes other than bullets or cannon balls. Japan's record in Manchuria is so remarkably unlike this that we shall do exceedingly well to study her methods with great care and give them effect in our own service. The dangers most to be dreaded in war are not those of the battlefield, but those of the camp. If we can learn from Japan, by all means let us take a leaf from her book."

Fourth Pan-American Medical Congress.—The Fourth Pan-American Medical Congress, which will convene in Panama the first week in January next, bids fair to be a most delightful mid-winter trip. The delegates will leave this country by the Atlantic, Pacific and Gulf coasts the last week in December. They will return by the same routes, or will make round trips. The Public Health Association meeting will take place on the following week in Havana, and those desirous of attending both meetings can arrange to do so. There are two routes for the physicians to take from Panama to Havana. The first is by way of Jamaica to Santiago de Cuba by boat and overland by rail to Havana. The second is by water from Panama to Vera Cruz and from there to Havana. The former will probably be the most pleasant trip. From Havana, the return trip can be made directly north to New York by water or via Miami or Tampa, Florida; or New Orleans. The connections and dates of sailing are now being arranged. The Panamanian Government has appropriated $25,000 for the Scientific Session and the entertainment. The Congress will be held from the second to the sixth of January. The afternoons will be devoted to the Scientific Sessions and the mornings and evenings to trips and social functions. So far as can be learned, the programme in Panama will be a reception on the first day, by President Amador of the Panama Republic, and the formal opening session of the Congress the same evening. On the second day, an excursion to the Canal in the morning, meeting of the various sections in the afternoon, and a banquet in the evening; on the third day, an excursion down the bay to Taboga Island, where a Panama breakfast will be served, scientific sessions in the afternoon and a ball in the evening. On the fourth day, an excursion to the U. S. Army barracks in the morning, section meetings in the afternoon and the formal closing session in the evening. On the fifth day, an excursion to the plantation of the United Fruit Company; and in the afternoon of this day, those of the congressists who intend going to Cuba to attend the meeting of the Public Health Association, will sail for Jamaica, while those who intend going by way of Vera Cruz, or returning home by way of New Orleans or New York, will remain until the following Tuesday. The Secretaries of the Sections of the Congress for the United States are: Doctors A. H. Doty, of New York, Hygiene and Quarantine; Judson Daland, of Philadelphia, Medicine; R. Matas, of New Orleans, La., General Surgery; Bert Ellis, of Los Angeles, Cal., Eye; Hudson Makuen, of Philadelphia, Throat; Frederick Jack, of Boston, Mass., Ear; C. H. Hughes, of St. Louis, Mo., Nervous Diseases; Geo. Goodfellow, of San Francisco, Military Surgery; John Ridlon, of Chicago, Orthopedic Surgery; D. W. Montgomery, of San Francisco, Dermatology; C. G. Kerley, of New York, Pediatrics; Noble P. Barnes, of Washington, D. C., Therapeutics; Walter Chase, of Boston, Pathology. Communications form physicians in the United Staes interested in these branches, can be sent directly to these different Secretaries. Delegates intending to attend the Congress, desirous of obtaining information concerning it, should communicate with the Secretary of the International Executive Committee in the United States, Dr. Ramon Guiteras, 75 West Fifty-fifth Street, New York.

Illinois County Regulations.—The following information will undoubtedly be of interest to every member of the medical profession in Illinois. It will certainly be of great value to those who assume the care of indigent patients. Under the law of Illinois, a liability is imposed upon counties to give or cause to be given such assistance as may be necessary to persons falling sick within the county, who are without money or property to pay for such assistance—in short, a county is liable for the necessary expense of medical attendance, nursing, provisions, fuel, etc., of a patient who is unable to provide for himself. It must be remembered, however, that a county is not liable for services rendered by a physician to an indigent patient—except in case of emergency where prompt and immediate action is required—or for supplies furnished to such patient by a physician or any other person, or a municipality, unless express authority to render service or furnish supplies has been given by an authorized county official, the Overseer of the Poor in Alexander, Calhoun, Cass, Edwards, Hardin, Henderson, Johnson, Massac, Menard, Monroe, Morgan, Perry, Polk, Pulaski, Randolph, Scott, Union, Wabash and Williamson counties, or the Supervisor or Overseer of the Poor in other counties, unless, perchance, the authorized county official should neglect or refuse to give or cause to be given to the patient such assistance as may be necessary, after the necessity therefor has been brought to his attention. It seems necessary to lay special stress upon these points, as, during the last few years, physicians have undertaken the care of smallpox patients without authority from the county and have sought in vain for the payment for their services. A few of these physicians had received authority from city and village officials to care for the patients in question. Since the municipal officials had not consulted the county officers in these cases, the county was not liable for the services rendered, and it is very questionable whether action against the city or village would hold. Another point which may be of great importance to the physician who undertakes to "look after" smallpox patients: The expense of enforcing health laws and quarantine regulations always falls upon the city, village or township concerned, and not on the county. In counties not under township organization, the expense falls upon the county in territory outside incorporated cities and villages. A township is not liable for expenses incurred within the corporate limits of a city or village, nor is the city responsible for expenses incurred within the township outside of the corporate limits of the city or village. An additional point which may also be of importance: A county is not liable for the expense of the care,

medical attention and supplies of a patient quarantined in his home, who has sufficient means to procure such care for himself. If a physician attends such a patient, he must look to him for payment for his services.

The Death-rate from Cancer and Appendicitis.—Dr. Tatham, in an analysis of the causes of death in the report of the Registrar-General for 1902, just issued, states that for England and Wales tuberculosis caused 57,396 deaths or 10.5 per cent. of the mortality from all causes; while alcoholism or delirium tremens caused 2,784 deaths. The deaths ascribed to cancer or malignant disease in the year under notice numbered 27,872, and exceeded by 2,384 the average number in the previous ten years corrected for increase of population. Of the above-mentioned deaths 13,540 were attributed to carcinoma, 1,690 to sarcoma, and 12,642 to "cancer" or "malignant disease" simply. Among males the crude rate of cancer mortality was 696 per million living, and was the highest male rate on record; among the other sex it was 985 per million, which had been the rate prevailing in the previous year likewise; this rate also was the highest on record among females. The mortality from malignant disease does not bulk largely in the bills of mortality until somewhere about the thirty-fifth year of life. It is right to mention, however, that at each of the six age-groups of the period under thirty-five years, the registered mortality from malignant disease is also increasing, and that not slowly. After giving a table showing the cancer death rates at all ages above thirty-five years—in England and Wales as a whole, in the urban counties, and in the rural counties—the rates in 1902 being compared with the average rates in the five years immediately preceding, he points out that if the cancer mortality at ages above thirty-five years be judged by the crude death rates the rural counties will appear to suffer much more heavily than the urban, whereas, if the corrected death rates be taken as test, the opposite conclusion follows, for the rural cancer mortality in both sexes is shown to be considerably the lower. But even this adjustment fails to reveal the true relative mortality in populations thus differently circumstanced. Appendicitis was the certified cause of the deaths of 901 males and 584 females—together 1,485, persons, in the year 1902, as compared with 1,244 in the year immediately preceding. Among males the death rate from this disease was equal to 56 per million living and among females to 34 per million, the rates in the previous year having been 47 and 30 per million respectively. Appendicitis was abstracted as a separate cause of death for the first time in 1901, previous to which year the deaths certified as from this cause were classed under the head of enteritis. There is little doubt that in past years many of the deaths registered as from peritonitis were really due to appendicitis. In compiling the tables for the year under present notice 154 deaths were contributed to the total of 1,485 deaths from this disease, as a result of medical inquiry, these 154 deaths having originally certified as from peritonitis.

OBITUARY.

Dr. William Wilson, of Jersey City, N. J., died on Wednesday, Oct. 26, in his seventy-fifth year.

Dr. Eleanor Louise Rundio, South Orange, N. J., died on Monday night at her home, of typhoid fever. She studied medicine in the New York Medical Hospital and College for Women, and graduated from there in 1902, after which she served as a resident physician for one year. She then went to the Lying-in Hospital, New York, and later took a course in the New York Ophthalmic Hospital.

Dr. Mordecai Price, one of the best known surgeons in Philadelphia, was found dead in his office October 29. The evening before he was in his usual health and performed an operation for appendicitis. He was found the next morning lying on the floor grasping his instruments, evidently dying shortly after reaching his office. Dr. Price was sixty years old. His preliminary education was obtained in New York, and he graduated in medicine at the University of Pennsylvania in 1869. For a number of years he has been associated with his brother, Dr. Joseph Price, in their private hospital on Eighteenth street.

Dr. Lewis Royer, of Pottstown, Pa., died of apoplexy October 26, aged eighty-two years. He had been engaged largely in the wholesale drug trade and in other busines affairs.

Dr. Davis G. Hetzell died in West Philadelphia, where he had practised more than forty years, on October 25, aged sixty-eight years. He was graduted from Jefferson Medical College in 1861 and served as surgeon in the Civil War.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, October 22.

AN X-RAY SCARE—THE PROPAGATION OF DEGENERACY—AN EPILEPTIC COLONY—THE PREVENTION OF CRUELTY TO CHILDREN—THE LATE DR. NIELS FINSEN.

In a previous letter reference was made to the sad case of Dr. Blacker, radiographer to St. Thomas' Hospital, who died of a spreading epithelioma of the arm originating, it was believed, in a burn of the finger caused by X-rays. The case was made the more tragic by the fact that Dr. Blacker successfully treated King Edward VII. for a small rodent ulcer of the face while he was himself actually in the clutches of a more terrible disease. The case was kept so secret here that few people know the facts. Recently, however, carefully veiled allusions to it have appeared in some newspapers in connection with sensational reports as to the prevalence of X-ray dermatitis among radiographers. These reports had their origin in a paper read by Dr. Hall-Edwards of the General Hospital, Birmingham, at the annual meeting of the British Medical Association held at Oxford in July. He there gave an account of the condition of his own hands which are covered with warty growths, cracks and ulcers that have resisted all treatment. The warts grow steadily and can be kept down only by rubbing with sandpaper or cutting with a razor. Great pain is experienced, and altogether the outlook is unpromising. Dr. Hall-Edwards states that several medical men have abandoned the use of the X-rays, in consequence of similar mishaps, and in a case of which he has personal knowledge, eighteen months' rest, with constant treatment, has produced but slight improvement. It is not only the hands that suffer. Several constant workers suffer from chronic dermatitis of the feet, which the boots have failed to protect. Dr. Hall-Edwards' paper, appearing as it did almost simultaneously with the news of the death of Edison's assistant, Clarence M. Dally, has, of course, been seized upon by the sensational press which sees in all this the opportunity of a "scare,"

that will fill their columns at this dull season. The flesh of the public is made to creep day after day with headlines, such as "Terrors of the X-Ray," "The X-Ray Peril," "A New and Painful Disease," "London Doctors' Terrible Sufferings," etc. It is stated that nearly all the doctors who are engaged in X-ray work in the London hospitals are suffering from dermatitis. Quite recently, we are told, one doctor, who is in charge of the X-ray department at one of the largest of the London hospitals, had the first two joints of the forefinger of his right hand amputated, and a few days ago it was found necessary to take the remainder of the finger away. To an interviewer the doctor confided that he had suffered the torments of the damned. From June onward, until he had his finger amputated he scarcely knew what sleep was. Night after night he rolled about in agony. "All the earlier workers," proceeded the doctor, "are suffering in greater or less degree; and this is due solely to the fact that we did not know what we were working with, and took no precautionary methods against possible danger." It is certain that X-ray dermatitis more or less severe is fairly common among operators; experience here agrees with what is reported from America. But the newspapers, as is their wont, have exaggerated both the actual mischief and the danger. Doctors engaged in X-ray work have learned the necessity of taking proper precautions, and there one hears but little of dermatitis among the younger men.

It is estimated that there are 50,000 epileptic children in the United Kingdom, and that one child in every 100 of population is feeble-minded. During the last few years special schools have been established in which such children are trained till they are sixteen. Then they are thrown on the world where they are left to shift for themselves. Most of them drift into imbecility, vice and crime, and flood the workhouses and prisons. They are thus a grievous burden to the community. By way of remedy it has been suggested that some public authority should be empowered to detain feeble-minded persons incapable of looking after themselves and place them in what may be called colonies of refuge, where they will be safe from temptation and where in particular they will not be allowed to propagate degeneracy. A conference of representatives of the National Association for the Feeble-Minded and the National Union of Special Schools was held on October 13 and 14, to discuss the steps to be taken to give effect to this proposal. A striking instance of the danger of allowing mentally defective children to be at large was given by Mrs. Burgwin, a lady who has taken a leading part in organizing special schools for such children in London. She said she knew in one district a family of seven children of whom three were physically defective, two mentally defective, one very bright and promising, and one apparently all right. The latter was a little boy, very alert, ready and fluent in expression. But his school teacher knew him to be mean and cunning. In the playground he was always pinching smaller children. It was impossible, however, to get him certified for detention, and one day the bright child of the family, aged four, was found drowned, and they felt morally certain that the cunning child had drowned her. But there was no proof, and he was set free. Every one sympathized with him. Two months later he took another child into an empty house, and, but for a passer-by, would have undoubtedly killed him. The boy is now confined as a criminal lunatic, but he ought, said Mrs. Burgwin, to be taken charge of as a mentally defective child. Feeble-minded children may, according to her, be divided into three classes: (1) Those who, after training, can return to elementary schools. (2) Those who remain in the special schools until sixteen. (3) Those who after trial are found to be non-educable. She urged that the third class should be certified and sent to permanent working colonies, but on no account allowed to be at liberty. If they were, the result would be that the public would have to keep not only them but their progeny. Terrible facts with regard to feeble-minded and defective women were given by Dr. Potts, of Birmingham. He paid a visit to a girls' night shelter, and investigated the first twelve cases he found there. The following is the record: 1. Consumptive, both parents died of the disease. 2. Neurotic drunkard, with a family who had suffered from St. Vitus' dance. 3. Normal. 4. Deaf and mentally defective. 5. Neurotic and mentally defective. 6. No congenital defect, but health ruined by drink. 7 and 8. Feeble character. 9. Suffering from persistent bad memory. 10. Twice imprisoned for theft; daughter of drunken loafer. 11. Normal. 12. Mentally defective and suffering from heart disease. Thus, out of twelve only two were normal individuals. Yet the ten were free to go as they liked, and to bring up defective children. "It is well known," said Dr. Potts, "that a large number of the inmates of penitentiaries are feeble-minded women." The cost of keeping such persons in colonies would be high, but small compared with the ultimate cost of keeping them and their progeny. In Birmingham he knew a feeble-minded woman selling matches who had nine times been in the maternity wards of the workhouse. Surely that was a disgrace to our legislation. The Magdalene homes, said Dr. Potts, are filled with girls in their teens, and out of ninety-seven cases he investigated he found 37 per cent. were mentally deficient. Yet there was no power to keep them out of the streets. The causes of mental defects Dr. Potts gave as: 1. Defective nutrition in early years of life. 2. Hereditary tendency to consumption. 3. Descent from insane or criminal stock. 4. Chronic alcoholism of one or both parents. "Is there any one who has inquired into the family history of inmates of prisons or reformatories who thinks," asked Dr. Potts, "that so long as the expenditure on drink in this country reaches the appalling total of £180,000,000 per annum, we shall free ourselves of this terrible incubus of criminals, epileptics, lunatics, neurotics, feeble-minded and defective persons?" A resolution was passed advocating that the optional law giving education authorities the power to open special schools for defective children should be made compulsory. Sir Robert Anderson, who, as a high police official, has had a large experience of defectives, complained that there was a false idea of liberty abroad with regard to such persons. "So long," he said, "as they keep their hands off our throats and out of our pockets, it is held that they ought to be at liberty to do as they like. That is a mistake. I would define liberty as 'the divine right of every man to do what he ought to do.'" "Why," he said, "does nature eliminate the unfit? To protect the community. Therefore, if we prevent the elimination of the unfit by training them we ought to protect not only them, but the community, by looking after them. To accord to the feeble-minded

all the rights of the citizen is the part of quasi-philanthropic lunacy. Is it not monstrous that there should be no restriction of the marriage of these feeble-minded people? The sham philanthropists have expended all their little stock of pity upon these poor objects, but they have no pity upon those they bring into the world. I have been represented as one of the most hard-hearted members of the community, but I say emphatically, our duty is to protect these feeble-minded people from themselves." Sir Robert Anderson went on to urge that the care of the feeble-minded should be raised into a national question, and that public opinion should be educated to accept a national scheme for the detention of such persons. A resolution in that sense was passed unanimously.

A good example of what can be done for the care of epileptics is afforded by the colony founded and maintained by the National Society for the Employment of Epileptics at the village of Chalfont St. Peter, in the county of Buckingham. In the homes there established some 200 epileptics enjoy the advantages of a regular life passed in healthy surroundings. Since the establishment of the colony in 1894 several homes have been added, but the accommodation has always been inadequate to meet the ever-increasing applications for admission. During the last year an administration house has been built at a cost of $25,000, contributed by a well-known philanthropist, Mr. Passmore Edwards. The new buildings were formally opened on October 20. Among those present were the King's physician, Sir William Broadbent, and Dr. Thomas Buzzard, the distinguished neurologist. Lord Rothschild paid a well-deserved tribute to the excellence of the work done by the National Society for the Employment of Epileptics.

On October 1 there came into operation a new act for the prevention of Cruelty to Children. Among the novel points in the act is a provision that any person having the custody of a child under sixteen years of age, who shall wilfully ill-treat, neglect, abandon, or expose such child in a manner likely to cause unnecessary suffering or injury to its health, shall be liable, on conviction, to a fine not exceeding $2,500, or imprisonment with hard labor up to two years. Further it is enacted that upon the trial of any person for the manslaughter of a child of which he has had the custody, the jury may find the person guilty of "an offence of cruelty." Further, if it is proved that a person indicted for an "offence of cruelty" is interested in money payable in the event of the child's death, and had knowledge that such money would thus become payable, the fine may be doubled and the alternative punishment increased to five years' penal servitude. It is forbidden, save in certain exceptional cases, to cause any child to be in any street or premises for the purpose of begging, or in any premises licensed to sell intoxicants for the purpose of singing, playing, performing, or selling between 9 P.M. and 6 A.M. Moreover, no person may cause any child under sixteen to be in any place for the purpose of being trained as an acrobat, contortionist, or circus performer, or for any other dangerous performance. In the 1896 act, this prohibition did not extend to parents who themselves trained the child. This exemption no longer exists.

Mr. Malcolm Morris, the real pioneer of the light treatment in this country, has been asked by the committee formed in Denmark for the erection of a monument to the memory of Niels Finsen, to cooperate with them by heading a British committee for the same purpose. Although there is much difference of opinion among physicians here as to the value of the light treatment, the movement will probably find considerable support, as it is sure to have the approval of the Queen, who is known to be a great admirer of her deceased countryman. Our people are in regard to royalty like the virgins who follow the lamb withersoever he goeth. Finsen, however, though he can scarcely be called a great man, deserves a monument for his devotion to work under the most discouraging circumstances.

URGENT ADENECTOMY.

To the Editor of the MEDICAL NEWS:

DEAR SIR: In the issue of the MEDICAL NEWS, October 15, 1904, Dr. H. Jarecki reports a case of urgent adenectomy during the progress of a pneumonia. Though the operator is to be congratulated upon his success, the method employed is extremely radical and open to a serious objection.

It must be conceded, and the point is appreciated by the author in the article referred to, that the removal of adenoids during the course of an inflammatory process in the bronchi or lungs is a hazardous procedure in any case, especially in an infant. Particularly so in view of the fact, that the object to be attained, viz., to give the patient nasal breathing, can be secured by a simpler and less dangerous method, one that can be employed by the attending physician.

Under ordinary circumstances, a moderate degree of obstruction due to adenoids can be relieved by instilling a mild warm alkaline solution into the anterior nose, or the normal salt solution may be used. A few drops of warm castor oil, vaseline or alboline will answer the same purpose.

Pneumonia is a frequent occurrence in infants and children with adenoids. The simple suggestions just offered, have been used with good results in numerous cases.

If the obstruction, however, is of a high grade, as was the case in Dr. Jarecki's patient, the plan referred to below may be tried.

Some years ago Dr. Goodwillie advocated the use of hard rubber tubes (nasal intubation) to relieve nasal obstruction. Others have modified the tubes, or rather, in their place, have advised and used drainage tubing of the proper length and caliber. A portion of a soft rubber catheter (Jacques or Nelaton) will answer as well, and is preferable as its surface is better finished. Properly lubricated, it can be easily passed along the flow of the nasal passages, as in nasal feeding, until the posterior pharynx is reached, the portion at the anterior nares is secured by means of a small safety pin, and the rest cut off. It may be done on one or both sides, or a tube may be kept in for a short time in one nostril and then changed to the other. It is surpising how readily relief is afforded. It may not be necessary to keep the tube *in situ* more than a few hours. Sometimes it can be used for days, taken out morning and evening to be cleaned. The recommendations are not theoretical. The writer has resorted to the plan (introducing catheter) in infants with lateral pharyngeal abscess and adenitis of Henle's glands, also in cases of infectious diseases complicated with nasopharyngeal exudation of false membrane and secondary cervical adenitis, etc. The method is simple,

it does not deserve to be termed an operation, is without danger, can be employed by the physician or trained nurse, and secures prompt relief. Furthermore, there is no large raw surface left, which (in an infant or young child whose vital powers have been lowered by the pneumonia poison) might easily permit the entrance of pathogenic germs and give rise to serious septic symptoms.

In the above remarks there is no intention to cast any reflection upon the management of the case. The operation was a brilliant success, moreover, the patient recovered. The object of this communication is merely to direct attention to a simple procedure, whereby a fair amount of nasal breathing can be secured without any dangerous operative measure. Of course it is understood, in such patients, the nasopharynx ought to be cleaned out subsequently. Such an experience as the one detailed above is a strong argument in favor of an early removal of lymphoid hypertrophies giving rise to obstructive symptoms. The operation should be done before the advent of dangerous catarrhal symptoms involving the bronchi or lungs. F. HUBER, M.D.

October 18, 1904.

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSOCIATION.

Twenty-first Annual Meeting, held at the Academy of Medicine, New York City, October 17, 18, 19 and 20, 1904.

THIRD DAY—WEDNESDAY, OCTOBER 19.

(Continued from Page 861.)

Original Dose of Antitoxin.—Dr. L. C. Ager, of Brooklyn, presented a sample of the original dose of antitoxin, as it was sent to this country when the serum was first introduced. The dose was about one-half of one c.c., and as the serum was very low in antitoxic quality, it can readily be understood how weak the remedy was. Now it is understood that the dose should be large. The American Pediatric Society decided some time ago that 2,000 units should be the beginning dose. This was a mistake. Dr. Ager thinks that at least 3,000 units should be used and many of the failures that are blamed on antitoxin are really due to too timorous use of the remedy. Dr. Ager considered that the only prejudice against antitoxin is with regard to its supposed liability to produce paralysis. This is due to some wild newspaper statements, and is unsupported by any evidence. He is glad to notice that Dr. Kerley advises the injection of the serum into the abdominal wall. The Health Department suggests its injection into the soft tissues of the back. This is almost sure to invite discomfort, at least, and may be the source of even suppurative condition with the child lying on its back. Personally he considers that injections into the mammary region in children are best, because there is least likelihood of sequelæ.

Infrequency of Intubation.—Dr. Francis Quinlan, of New York, said that before the introduction of antitoxin, he had to do many intubations, and tracheotomies. In one year he did 116 intubations. Now the necessity for this is very rare. The entire use of antitoxin did away with the necessity for the practice. Antitoxin is a physiological remedy that exactly meets the indication. It is the only one in the whole range of medicine. It seems too bad that there should be any opposition to it, yet there still remain some physicians who do not favor its use.

Appearance of Membrane.—Dr. Louis Fischer, of New York, said that a large dose of antitoxin should be given at once when the disease was recognized, and then the appearance of the membrane, together with the temperature and pulse, must be the guide to repetitions of the remedy. Not less than 5,000 to 10,000 units should be given as an initial dose. This is the custom at the Willard Parker Hospital. It should be given until its effect is produced. As soon as the membrane assumes a granular appearance and begins to disintegrate, the victory has been won. Nasal diphtheria is quite as bad as laryngeal diphtheria, and the initial dose should be at least 10,000 units repeated if necessary. Antitoxin must not be relied on alone, however, but the children must be fed freely so as to improve their nutrition and increase their resistive power. The antitoxin does not kill the Klebs-Löffler bacillus and has no effect on it. The resistive vitality of the tissues must be aroused to oppose further invasion. The bowels should be stimulated and the kidneys and the other emunctories, and the little patient should be kept in perfectly fresh air, as far as possible.

Opposition to Antitoxin.—Dr. Jas. J. Walsh, of New York, said that a certain amount of opposition to antitoxin still existed in spite of all that had been accomplished. It is found much more among the educated classes, especially newspaper men and literary workers. It is evidently due to the fact that the antis know how to get into print with their effusions. The antivivisectionists are also as a rule rabidly opposed to the use of serum therapy, because they fear the torture of the animals in its preparation. They discredit all the favorable reports and in their journals in this country and England keep repeating the story of any deaths that have taken place during the use of antitoxin and attribute all postdiphtheric palsy and nephritis to its use. By realizing the exact location of opposition more can be accomplished in meeting it. The antivivisectionist crusade against antitoxin is doing more to hurt their cause than anything else because mothers learn the value of it after use in the family and the philanthropically inclined see its benefits in hospitals. These points should be insisted on by family physicians who are interested in the progress of serum therapy and the defeat of the antivivisectionist movement as regards its extreme features.

Spraying the Throat.—Dr. Kerley said, in closing the discussion, that free spraying of the throat with diluted hydrogen peroxide seemed to be the best method of getting rid of the bacilli, which remained after the clinical symptoms of diphtheria had disappeared. During the progress of the disease, such spraying does not seem to be of special benefit, but in a convalescent period it should always be employed. To his mind the important principle with regard to the use of the antitoxin, is that not the diphtheria in general must be treated, but the individual patient and the conditions that are found in the individual case. The tendency should rather be toward large than small doses.

Radical Cure of Hernia in Children.—Dr. William B. Coley, of New York, reported the results obtained by Dr. William T. Bull and himself in 1,400 operations for the radical cure of hernia in children, performed at the New York Hospital for Ruptured and Crippled from 1891 to 1904, altogether 49,000 cases of hernia were under observation. Of these 47,000 were inguinal hernia. 4,000 cases of hernia oc-

curred in patients under fifteen years of age. Of these about 1,400 were operated. The others were treated by means of trusses and other means. Most of the cases operated on were very large hernias in whom trusses had been tried and failed or in whom there was a frequent tendency for the hernia to descend in spite of the truss. As a rule trusses were worn for one to two years before the operation was done.

Age for Hernia Operation.—Under four years of age, the radical cure of hernia by operation does not seem advisable. Young children frequently are cured of their hernia by the use of a truss or by other simple means. After this age, the use of the operation becomes more and more advisable, especially in the dispensary service, where proper care cannot be taken of such cases at home. One thing seems of special interest, viz., that there are many relapses after the cure of hernia by means of truss. In adults it is not an infrequent story that they suffered from hernia as children, which was cured, and then later on the relapse. Some surgeons advise operation even in infants, but the truss is better. Congenital hernia is probably never cured by means of the truss. In cases operated by the Bassini method not a single relapse has occurred, though the cases have been traced for from two to eight years. In inguinal hernia in female children, the round ligament is sometimes allowed to remain in its usual location, yet the absence of relapses shows that the cord transplantation, considered so important in the male, is not always absolutely essential. Of course, the cord in children is smaller than in adults, and the round ligament is usually very small, so that this has its influence. In adults it seems advisable always to follow the Bassini method completely. None of the veins of the cord are ever excised. The lessening of the diameter of the cord may be necessary in the Halstead method of radical cure, but not in the Bassini. At times the excision of the vein is followed by atrophy of the testicle, an extremely undesirable sequela. The tissues are brought together by means of kangaroo tendon, as introduced by Dr. Marcy, of Boston. This keeps the tissues firmly together until union takes place, and then is well absorbed. Whenever the appendix is found to be adherent to the sac, it is removed. It is never specially looked for, however. Some relapses took place in cases of sliding cecal hernia in which there was no proper neck of the sac to tie. Four deaths took place in 1,460 cases. In the first double pneumonia carried off the patient on the fourth day. In the second at autopsy, a septic condition was found after a long and serious operation requiring considerable handling of tissues in the days before the introduction of rubber gloves. In the third cases there was very serious complicating Pott's disease, and the patient died of acute pericarditis on the eighth day. This case would not now be considered suitable for operation. The fourth death took place after an operation performed by an assistant surgeon who was not so familiar with the technic of the radical operation, and the operation took more than an hour and a half. This delay gave occasion for air infection, while the bruising of the tissues during the lengthy manipulations reduced the resistive vitality.

Suture Material.—Undoubtedly the kangaroo tendon is the best. The asepticity of ligatures used to be considered the only quality worth thinking of. As McEwen remarked at the last meeting of the British Medical Association, this is only one of the qualities of ligatures, and not the most important. The ligature material must hold long enough to bring about union of tissues and then should be rapidly eliminated. Wire sutures are eminently inadvisable. In some cases where they have been used, subsequent strangulation has been found to occur in a loop of th wire. In the 1,460 cases operated upon, there were six relapses. Four out of the five of these occurred in patients in whom the cord had not been transplanted. They were done before the day of the Bassini operation. In the sixth failure, the case was one of sliding hernia. Most of the relapses take place during the first six months. Ninety per cent. of them during the first year, which is also the experience of other operators. In 600 cases, operated upon in patients between the ages of one and twelve years, there has been no relapse.

Dr. Wiggins said that kangaroo tendon is undoubtedly a most valuable suture material. He has recently had a severe test case in which to try it. A woman who was three and a half months pregnant had to have a laparotomy performed. The pregnancy was not interrupted and the avoidance of a hernia seemed almost impossible. Kangaroo tendon was employed, however, for the suture material, and the wound healed in excellent shape, and the pregnancy went on to its full term without any complications and without any sign of yielding on the part of the abdominal scar.

Dr. De Garmo said that in his experience radical cures for hernia in children had better be delayed until the patients are over four years of age. He has done 1,162 operations, 220 of them in children, and has had no relapses in children. In children undoubtedly hernia can sometimes be cured by means of the truss. In hernia in male adults, it is sometimes advisable to remove some of the vein so as to make the cord of less size.

Dr. Coley said, in closing the discussion, that after the truss has been given a fair trial, operation for the radical cure of hernia should not be delayed too long. Congenital hernias are apparently not cured by the use of the truss. In those that are cured, relapses sometimes take place, certainly much more readily than after radical operation. It is better then to operate as soon as it is decided that the truss will not prove curative.

Infant Mortality in New York City.—Dr. Lewis C. Ager, of Brooklyn, discussed the infant mortality statistics of Greater New York, remarking, as an introduction, that while figures cannot lie, lies can and do figure in statistics on many occasions. Of the 21,000 deaths in New York City during the past year, over one-fifth were in persons under one year of age, and nearly one-third were under five years of age. Most of the deaths among young children were from diarrhea, and the majority of them took place during July and August. While the general death rate has been constantly increasing, the mortality rate has not always corresponded to this increase among children. In 1902 there were 3,200 deaths; in 1903, 2,755 deaths, while in the summer just past, there were 3,800 deaths. The improvement that has come in the death rate must be attributed to the inspection of tenement houses and the milk supply and to the work of the Milk Commission. The best work can be done in educating the people to a knowledge of the important factors in infant healing.

Comparative Infant Mortality, Brooklyn and New York.—Up to 1891, the mortality rate favored Brooklyn. Since that time it has been against Brooklyn, and more deaths have taken place in proportion to the population than in Manhattan. What seems a curious paradox is to be found in the statistics of deaths from diarrheal diseases in the component parts of Greater New York. During the period when 170 deaths were reported in New York County, there were 209 in Kings

County, 216 in Queens County and 228 in Richmond County. This is exactly the opposite of what would be expected since overcrowding of population is supposed to be a factor in diarrheal diseases. The infant mortality in Brooklyn is worse than in New York, and this is due to the fact that condensed milk is used much more frequently in Brooklyn than in New York. In 250 infants deaths carefully traced in Brooklyn, about 60 per cent. of the little patients had been fed on condensed milk. Among the same number in Manhattan only 27 per cent. were fed in this way. Children fed on condensed milk, even when not actually ill, lose their resistive vitality. Another factor in the increased infant mortality in Brooklyn lies in the circumstance that here is practicaly no disposition of free ice among the poorer classes across the river and philanthropy has done very little to supply them with Pasteurized or otherwise sterilized milk.

Prostatectomy in Emergency.—Dr. John F. Erdmann, of New York, said that in all emergency drainage of the bladder in old patients, he preferred to do a prostatectomy and drain through the perineum. Formerly such drainage was apt to be suprapubic, and there were many accidents that might take place. Such drainage is contra-indicative only in extensive malignant disease of the prostate with great enlargement. The dangers of the perineal operation are not near so great as the suprapubic method. There is never the profound sepsis that occurs by the former method. Patients do not have to lie down, but may sit up not long after the operation, and may even walk about on the fifth day. The pressure while sitting up brings the edges of the operation wound together and aids recovery.

Dr. R. H. M. Dawbarn, in discussing Dr. Erdmann's paper, said that emergency prostatectomy with drainage through the perineum was a very valuable surgical procedure. It has a better technic than the older method and gets directly at the condition. The after-results are uniformly better.

Oxygen and Chloroform in Anesthesia.—Dr. James Taylor Gwathmey, of New York, discussed the value of oxygen in combination with the different anesthetics in common use. In his recent experience oxygen with chloroform has given specially good results, so much so that he considers it deserving of special investigation by a commiteee. He was enthusiastic as regards its freedom from danger, from complications and inconveniences of all kinds. At his suggestion, it was directed that the president appoint a committee to investigate further this imporant subject.

The Heart in Scarlet Fever.—Dr. Louis Fischer, of New York, read a paper on scarlet fever with remarks on the temperature as a guide in estimating the prognosis and the development of complications. He said that while the temperature is usually considered an infallible sign of the patient's condition in scarlet fever, it cannot always be depended on. Malignant scarlet fever may occur with apparently no temperature. Mild scarlatina with a temperature of 103° to 104° F. is not unusual. Very high temperature is not absolutely unfavorable. Fever alone is not the indication of the disease. The same thing is true in other children's affections. Dr. Fischer has seen empyema with a normal temperature. Other suppurative conditions may exist for days without causing serious disturbance of the temperature current. Hence the inadvisability of depending absolutely on the temperature. At times the toxins of the disease seem to inhibit the thermic centers, and there is very little disturbance of temperature.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirtieth Annual Meeting, held at Cincinnati, Ohio, October 11, 12 and 13, 1904.

(Continued from Page 864.)

The Mamma: Its Physiological Purposes.—Dr. Thomas H. Manley, of New York, discussed the coarse and finer anatomical elements of the mamma in their bearing on some of its pathological affections. He drew the following conclusions: (1) The mamma is a highly organized and structurally a most complex organ. (2) Its functions are manifold. It is an essential and integral part of the generative system. Intermittent in function, like the testes, total ablation, like double castration, makes its impress on the sensorium. (3) Very frequently degenerative or pathological changes begin in a single isolated lobe, about twenty of which are in each breast. In all non-malignant affections, radical measures should be limited as far as possible to the affected area or lobe. (4) It is only in malignant disease of a progressive type and life is imperiled that total sacrifice of the breast is justifiable. (5) Inasmuch as the functions and purposes of the axillary lymph ganglia are yet imperfectly understood, and their removal, quite invariably enhances the risks of operation involves a wide mutilation of the chest walls, and always leaves more or less impediment in shoulder action, or even at times a painful tumefied limb, it is only as an extreme and exceptional measure that their complete extirpation should be practised.

Intestinal Surgery, with Remarks on Technic.—Dr. John Young Brown, of St. Louis, said there was a class of abdominal cases which might justly be considered acute, for the reason that the indications for immediate surgery were mandatory, and in which the mortality largely depended upon the time of operation and the technic of the work. He discussed, first, penetrating gunshot and stab wounds of the abdomen; second, severe abdominal contusions associated with rupture of intestines or other visceral injuries; third, strangulated hernia, confining himself as nearly as possible to a consideration of the operative technic, citing cases in point.

Gastro-enterostomy.—Dr. William H. Wathen, of Louisville, Ky., in this paper described all the pathological conditions indicating the necessity for stomach drainage by the several methods that had been practised for this purpose. He said pyloric divulsion had proven unsatisfactory, seldom gave permanent results, and sometimes committed a traumatism that increased the trouble. Pyloroplasty and its modifications had given better results, but the operation was seldom indicated and was practically obsolete. Gastroduodenostomy, and especially the modification by Finney, was theortically ideal, and in properly selected cases gave excellent results, but it was often impractical because of adhesions or tumors, and could not be generally adopted; its simplicity could not recommend it, because gastroenterostomy might be performed as easily, as quickly, and with a mortality as low, and was applicable in nearly all cases. Wölfler's anterior anastomosis and von Hacker's posterior anastomosis with their modifications were the two methods generally adopted, but Roux's method of cutting the intestine across, implanted the distal end into the stomach, and the proximal end into the side of the distal end was theoretically ideal, and avoided regurgitant

vomiting, but it was difficult and prolonged, and if universally accepted would have a mortality that would be prohibitory. Gastro-enterostomy by the surface to surface anastomosis of the stomach and the jejunum was applicable to the greatest number of cases, and might be performed in nearly any condition requiring stomach drainage. Anterior gastro-enterostomy as an operation of election must very soon become obsolete, and would finally be accepted only where an operation was necessary to give temporary relief, or where the posterior operation was contra-indicated, because of adhesions and the feeble condition of the patient that demanded a quick operation. The ideal operation of election must eliminate the intestinal loop, and this might be done by the posterior method, by attaching the jejunum very near its origin under the transverse meso-colon; the bowel incision might then be made longitudinally or transversely, but was usually made in a longitudinal direction, Kocher and Mikulicz making transverse incision. This method was preferable if the opening into the bowel could be made large enough to permit of continued unimpeded drainage, but the anastomosis was more difficult than in the longitudinal bowel incision. Posterior gastro-enterostomy was now the accepted method with Robson, Mikulicz, Kocher, Czerny, Moynihan and Mayo, with no higher mortality than the anterior method, with nearly an absence of regurgitant vomiting and other immediate complications, and with ultimate excellent results in drainage, the gastrojejunic opening seldom contracting enough to induce pathological condition. The McGraw ligature in the anterior method gave good immediate results, but we could not judge correctly of the ultimate results in the patency of the gastrojejunic opening, and the ligature had probably not been tested in the posterior method. The Murphy button had the advantage of being quickly applied, but except in selected cases possessed no advantages over the suture, and was more frequently followed by complications.

The Indications and Limitations of Various Operations on the Gall-Bladder.—Dr. Charles A. L. Reed, of Cincinnati, Ohio, reviewed the various operations usually performed for the relief of surgical conditions of the gall-tract, summarizing them under the heads of cholecystotomy, cholecystectomy, cholecystenterostomy, and choledochotomy. He recounted his experiences during the last fifteen years, first with cholecystotomy, and cited cases to show that operation had distinct limitations, and urged that it ought not to be done in cases in which prolonged drainage was required, or in which there was a demonstrable permanent obstruction in the common duct, or in cases in which there was reason to suppose that such obstruction might develop. He insisted that the gall-bladder exercised functions of importance in the human economy, and that consequently it ought not to be removed without adequate cause. He recognized as legitimate indications for cholecystectomy conditions of atrophy and malignant degeneration of the gall-bladder and cases in which benign neoplasms caused practical obstruction of that viscus; but insisted that the operation ought never to be done when the gall-bladder could be restored to functional integrity with safety to the life and health of the patient. He urged that cholecystenterostomy should be considered the operation of choice in all cases in which the gall-bladder and a desirable segment of the intestinal tract, preferably the duodenum, the ileum, or the jejunum, in the order mentioned, should be approximated, and in which drainage was demanded for accumulations within the gall-bladder of whatever character; for occlusion of the common duct or following operations upon it; for cholecystitis in which the gall-bladder could be safely left *in situ*, and in all chronic fistulæ of the gall-bladder. It ought, also, to be employed to complete an anastomosis in cases in which nature had atempted to accomplish the task by the formation of firm adhesions between the gall-bladder and the intestines.

Ectopic Pregnancy.—Dr. F. F. Lawrence, of Columbus, Ohio, reported cases of ectopic pregnancy. In ectopic pregnancy the death-rate should be lower than in appendicitis, providing the surgeon got the cases before rupture. The diagnosis of tubal pregnancy before rupture should be made with as much or greater certainty than could a normal pregnancy before the third month. The fact that a tubal pregnancy was allowed to go on to rupture was a reproach to obstetric practice, first, because of indifference or carelessness which prevented proper investigation of the case early. This might be on the part of the patient or physician, but the real fault lay in the indifference to obstetrics which had permitted women to look upon pregnancy as a simple matter, and not one demanding the attention of skilled service except in complicated labors. In unruptured cases the tube could be more safely removed through abdominal incision. In ruptured cases he was convinced that it was often very unwise to attempt to remove a patient to a hospital. The chances of infection in her home could be more readily overcome than the danger of increasing hemorrhage by handling. In all cases of extrauterine pregnancy, tubal disease, which was bilateral, seemed well established. The danger of a catastrophe in case the unaffected tube was left was therefore great, unless that tube be safely obliterated. Absorbable ligature was not a safe material to use for obliteration. Silk of large size only should be used. The better practice was to remove both tubes, retaining the ovary, if possible.

Etiology of Ectopic Gestation.—Dr. H. B. R. McCall, of Kansas City, Mo., read a paper on this subject, in which he discussed the genealogy of ectopic gestation relative to evolution. He submitted classifications, reported cases, and made a plea for early diagnosis, and operation, with special reference to etiology and diagnosis.

Brain Abscess of Otitic Origin.—Dr. George F. Keiper, of Lafayette, Ind., reported cases of brain abscess of otitic origin, and made some observations concerning brain abscess in general. Case I was an abscess of the right temporosphenoidal lobe. Recovery. No symptoms of brain lesion. No abscess suspected. Operation made for mastoiditis. Removal of necrotic bone forming the roof of mastoid antrum revealed abscess. No symptoms of aphasia. Case II. This case had longstanding otitis media, recurring frequently, and had often complained of pain on mastoid, which at those times was tender to the touch. When first seen, patient was comatose, with convulsions recurring frequently. Patient had had sixty in twenty-four hours prior to the author's first visit. The mastoid was opened, but no pus was found. He continued opening the skull upward over the temporosphenoidal lobe. Dura bulged. He incised freely, giving vent to flocculi and serum. Patient had but two convulsions

since. Regained partial consciousness, but died in forty-eight hours after operation.

Foreign Bodies in the Cornea.—Dr. Dudley S. Reynolds, of Louisville, Ky., said that injuries of this character should be classified according to the depth of penetration and extent of surface. The foreign bodies should be classified as metallic, ligneous, vitreous, and calcareous. Of whatever character they might be, no kind of foreign substance should be left long in the cornea. Where the epithelium alone was involved, the injury should be classified as severe. Wounds penetrating the anterior elastic layer, even though of very limited extent, should be classed as grave. Those which penetrate through the cornea should always be regarded as perilous. Treatment of the serious, the grave and the perilous varieties should conform with some general preconceived plan.

The Transverse Fascial Incision for Operations in the Pelvis.—Dr. Emil Ries, of Chicago, contributed a paper on this subject. In order to gain reliable fascial protection for incisions for pelvic work, it was desirable not to have to incise the fascia in the median line. Pfannenstiel's method was a useful improvement where the organ or tumor to be removed was not large. It began with a transverse incision through skin, fat and fascia. The fascia was then dissected up from the recti and raised as a flap with fat and skin. The recti were then separated and peritoneum incised in the median line. After the operation in the pelvis was finished, the peritoneum and recti were sutured in the median line, the fascia and skin transversely. The author had used the incision for various operations on the tubes, ovaries, uterus, appendix, and reported favorable results.

Suppuration of Nasal Accessory Sinuses.—Dr. J. A. Stucky, of Lexington, Ky., pointed out the importance of early recognition of suppuration of nasal accessory sinuses. Frequently peculiar anatomical inter-relationship of the different sinuses, when involved in suppuration process, rendered the symptoms obscure and misleading. Suppurative products might exist in latent form, giving rise to no local symptoms, and eventually resulting in systemic infection. Chronic inflammation in a closed cavity had a tendency to pus formation. He reported fatal cases due to absorption of pus or the invasion of suppurative inflammation through the optic foramen or holes in the cribriform plate to the base of the brain. The sequelæ of chronic suppuration of any accessory sinuses were frequently due to some form of neurasthenia and migraine. An increased number of cases were probably due to grip, pneumonia, and strenuous indoor life. The treatment was the same as for pus formation in any other part of the body, this is, free drainage. The middle turbinate most frequently caused obstruction of natural openings or a hindrance to free drainage, and the early removal decreased the necessity for more extensive and radical operation later.

Strictures of the Urethra.—Dr. A. Ravogli, of Cincinnati, Ohio, said that urethral strictures were affections of localized tracts of the mucous membrane and of the submucous layer of the urethra, resulting often from gonorrhea, and not rarely from trauma or from traumatic urethritis. The symptoms were mostly local, but at times they might be the cause of general symptoms and of neurasthenia. Strictures were of different varieties, spasmodic and organic. The organic strictures were to be divided into wide and narrow, the latter being the result of the former. Both were the cause of impairment of micturition and of the production of inflammatory symptoms of the genito-urinary organs. Strictures were somewhat diminishing in their frequency, and this must be credited to the recent method of treatment of gonorrhea. In their treatment, one might expect a great deal of benefit from systematic dilatation and from remedial applications, but in some very serious cases external urethrotomy was imperative.

The Perilous Calms of Appendicitis.—Dr. Robert Wallace Hardon, of Chicago, read a paper on this subject, in which he presented the following conclusions: (1) Defervescence of symptoms and apparent better condition of the patient do not always mean recovery, but may be the forerunner of a dangerous condition. (2) As there is no specific for the disease, no matter what treatment is used, the one who procrastinates should shoulder the responsibility for the death. (3) When a clear diagnosis is made, but one treatment should be advised, that of operation as soon as possible under the conditions, or the golden opportunity may be forever gone. (4) The physician who does not explain the great dangers of delay and the small comparative danger of operation, is doing his patient a serious injustice which often leads to fatal results. (5) Operation at the proper time usually greatly shortens convalescence, and eliminates all danger from this cause thereafter. (6) Procrastination is the greatest cause of surgical death, operation often being performed as a last resort when little hope of recovery exists.

The Prevention of Appendicitis.—Dr. William M. Harsha, of Chicago, stated that from available figures it would seem that this disease was more frequent in America than elsewhere. This was on the assumption that the mortality rate was much the same in England, Germany and France, where modern methods of medical and surgical treatment were practised, and where statistics were or should be reliable. In England and Wales, with a population of about 33,000,000, there were 1,244 deaths from appendicitis and perityphlitis in 1901, or 38 per million. In 1902 there were 1,485 deaths, or 45 per million. In Illinois, with a population of about 5,000,000, there were in 1903 471 deaths from appendicitis, or 94 per million. In Chicago alone, which represents nearly two-fifths of the population of the entire State, there were 249 deaths in 1902, and 260 in 1903, being at the rate of 140 per million. The same high death rate was approximated in other cities of the United States, especially in similar latitudes. New York City had, in 1903, 439 deaths, or 123 per million. Statistics of deaths from this disease in various cities, both at home and abroad, were given. Considering the causes that might be influenced by treatment, the author believed errors of diet were the most frequent. The disease occurred most frequently at the age and in the sex in whom faulty habits of eating and errors of diet were most common, from ten to thirty years. It was common to see attacks follow an immoderate meal, or the ingestion of indigestible articles of food. If one had transgressed in either of these ways and felt the approach of an acute digestive disturbance, the rational treatment was the prompt evacuation of the whole digestive tract, keeping it empty, and urging strict recumbency. Cholera morbus ushered in many cases of appendicitis, which were regarded as the primary trouble. The acute digestive disturbance, irritating the mucosa, was followed by stenosis of the base of the appendix and the infection ensued. This he had observed formerly in a considerable general

practice. While fecal concretions or foreign bodies were less frequent causes of appendicitis than was formerely supposed, they caused probably ten per cent. of cases. As to treatment, the individual case must be considered by itself, its etiology carefully studied, as well as any peculiarity, and treatment adapted accordingly. In one case it would be necessary to regulate the habits of eating, in another to cultivate immunity from colds or proper habits of exercise, while digestive disturbances of various kinds would require attention in others. In all the proper hygienic conditions should be secured to keep the vital resistance up to the highest point. During the past six or seven years he had advised these measures as preventive after one attack in which there had been no operation, and so far as can be known, he believed recurrence had not occurred in over 20 per cent., most of these being in young people, partly because of the greater frequency in the young, and in part he believed because of lack of intelligent cooperation on the part of the patient. The consensus of opinion was that more than 50 per cent. of the cases not operated upon recurred.

The Mortality of Appendicitis.—Dr. Channing W. Barrett, of Chicago, read an interesting statistical paper on this subject, which was accompanied by a series of tables. Table 1 showed that Chicago still had a mortality in appendicitis about equal to .01 of the mortality from all causes. Table 2 showed that the percentages of female mortality from appendicitis varied very little from the percentage of female mortality from all causes, and that appendicitis was to be looked for as common in the female, notwithstanding the old belief that it was rare. Table 3 showed the greatest mortality at the best period of life, early adult life, the greatest number dying at any one year of age being 22 at the age of nineteen years, the average age for all deaths being 26.54 years. Table 4 showed that leaving out the chronic cases the average duration of the disease in the 372 cases in which the time was mentioned was 8 33-76 days. Murphy's mortality cases showed that the average time after operation until death was 2.8 days. This demonstrated that his vast number of fatal cases were operated upon at the end of the sixth day, while all authorities conceded that an operation on the first or second day was safe and desirable. Table 5 showed that the most frequent cause of death from appendicitis was suppuration of the appendix, caused by perforation, gangrene, or passage of the infection through the wall, and peritonitis; and, further, that adhesions and obstruction were common. Many cases did not have the advantage of hospital treatment or an operation. An early diagnosis was more desirable, yet the Bureau of Vital Statistics considered that a diagnosis was not made at all in 105 cases; a few of the remainder were made by the Coroner. Some were made post-mortem, and one could never know how many were made too late for any operation to save life. The long, but only partial, list of vague diagnoses copied from the death certificates showed that in all probability some cases escaped detection. The author submitted the following conclusions: (1) An early diagnosis is of the first consideration. (2) All troublesome appendices should be removed without waiting for an acute attack. (3) All acute cases should be dealt with surgically in the interval between the onset of appendicitis and the dangerous rupture, without waiting for pus outside the appendix, for peritonitis, for adhesions, or for a possible but remote interval. (4) Cases of perforation or gangrene, with localized abscess, should be operated with drainage or removal of the appendix, according to the judgment of the operator. (5) Cases with perforation or gangrene without a wall of adhesion are in still greater need of an outlet for the infection to lessen the tendency of infection to travel inwards. (6) Price, Murphy, Hawkes, and others have shown a better percentage of recovery by the operative treatment of acute perforative peritonitis. (7) A case of acute appendicitis should be operated upon at anytime if the patient's condition will admit of an operation, unless the case is rapidly and beyond a question of doubt convalescing. In this latter case we should wait until all acute symptoms have passed. (8) Healthy appendices should be left alone. (9) Proper treatment does not contraindicate the use of stomach lavage, or the withholding of food, and when proper, these things should be employed, with or without operation. (10) Life is not the only consideration. The time of cure and after conditions are important. A case going through an acute attack without operation is saved by the adhesions. Adhesions are life-saving for the time, but they may be death-dealing afterward. The waiting treatment favors adhesions; early operation avoids them. An early operation sends the patient home in from ten days to three weeks. Twelve cases treated by the rest treatment, reported in the *Journal of the American Medical Association*, June 22, 1902, show an average of 60 7-12 days from the onset of the disease to the discharge of the patients from the hospital.

Remarks on the Etiology of Fissure in Ano.—Dr. J. Rawson Pennington, Chicago, said that a fissure might be located at any point in the circumference of the anal canal. Its most frequent location, however, was near the posterior median line. No satisfactory explanation for this fact had been given; neither had anyone proffered a satisfactory reason why it occurred in the anterior quadrant in less than one per cent. of the cases in males, and in more than eight per cent. of the cases in females. It seemed to the author that the theories usually taught and accepted as the cause of this disease were, at least in many cases, erroneous, and that we should have a more comprehensive etiology. He regarded the location of the ulcer as anatomical, and depended principally upon the support given to the tissues of the anal canal by the sphincters and levatores ani muscles. When the canal was overdistended, the dorsal surface received the least support from these muscles, the anterior the next, while the sides received the greatest. At the terminal portion this relative support is due to the difference in the distance between the posterior commissure and the tip of the coccyx, the origin of the external sphincter, and the tendinous center of the perineum, its insertion and the anterior commissure. Because of this difference, the posterior fibers of the muscle are more deployed than those of the anterior. Hence, when pressure was made from within outward it was obvious, since muscle fibers were easier separated or split than broken at right angles, that the weakest point in this muscle was at or near the posterior commissure; the next weakest point was at or near the anterior commissure. This latter point was weaker in women than in men. The lateral quadrants or sides received the greatest support from this muscle. Anatomical conditions and relations, almost identical with these, existed between the levatores and the proximal portion of this canal. Therefore, when this canal was placed under sufficient stress to rupture its tissues, the tear, all things being equal, should occur first on the dorsal surface, as it received the least muscular support; second, on the anterior surface, as it was the next weakest point, and, third, or last, on the sides. This was the sequential order in

which the respective tears of this canal should and do occur, and they not only corresponded with the weakest points in the muscular cylinder that surrounded and supported these canals, but with the statistics of the sequential location of fissure in ano.

The following papers were likewise read and discussed: "Causation and Radical Cure of Quinsy," by Dr. John F. Barnhill, Indianapolis, Ind.; "Cranial Injuries," by Dr. Shelby C. Carson, Greensboro, Ala.; "Internal Hemorrhoids, and Their Treatment," by Dr. Wells Teachnor, Columbus, Ohio; "A Case of Bilateral Tic Douloureux, treated by Removal of the Right Gasserian Ganglion and the Left Inferior Dental Nerve," by Dr. W. O. Bullock, Lexington, Ky.; "Hernia of the Tube," by Dr. Frank T. Andrews, Chicago.

Officers.—The following officers were elected for the ensuing year: President, Dr. Bransford Lewis, St. Louis, Mo.; First Vice-President, Dr. Frank P. Norbury, Jacksonville, Ill.; Second Vice-President, Dr. J. Henry Carstans, Detroit, Mich.; Secretary, Dr. Henry Enos Tuley, Louisville, Ky., re-elected; Assistant Secretary, Dr. John F. Barnhill, Indianapolis, Ind.; Treasurer, Dr. S. C. Stanton, Chicago, Ill.

Indianapolis, Ind., was selected as the place for holding the next annual meeting; the time, second Tuesday, Wednesday and Thursday in October, 1905.

NEW YORK NEUROLOGICAL SOCIETY.

Regular Meeting, October 4, 1904.

The President, Pearce Bailey, M.D., in the Chair.

A Case of Unverricht's Type of Family Myoclonus, But Without Epilepsy.—This was presented by Dr. L. Pierce Clark. The patient was a married woman, twenty-six years of age, of Irish descent. There was a family history of myoclonus in the father, uncle and sister; of facial tic in a grandmother, of hysteria in the mother and paralysis agitans in a great-aunt. The patient was well until her seventh year, at which time the myoclonus began. It consisted of arhythmic, clonic spasm of the left sternocleidomastoid muscle, and gradually spread into the entire left shoulder girdle, as well as the arm, trunk and thighs. Subsequently, the right side became affected in a similar manner. The muscles most markedly affected were the sternocleidomastoid, the trapezius, the deltoid, biceps, latissimus dorsi and glutei. The right side was most involved. Emotional excitement, embarrassment and anxiety increased the spasm. The gait was at times affected. The spasm was quieted by lying down. For the past eight years the spasm had been more or less continuous, with varying grades of paroxysmal intensity. It ceased during sleep. Speech was occasionally affected and swallowing was at times difficult. Laryngeal sounds were occasionally emitted. The patient had never suffered from epilepsy or from any attacks epileptoid in character.

Dr. B. Sachs asked how a case of this character could be distinguished from the *maladie des tic convulsifs*, to which the clinical picture bore a close resemblance? In Dr. Clark's case there did not seem to be anything more than a generalized convulsive tic, and without a distinct history of epilepsy he did not see how it differed from the affection described by the French writers.

Dr. Clark, in closing, said the question raised by Dr. Sachs had given rise to considerable discussion between the French and German schools. The case resembled Unverricht's type of family myoclonus in that the movements of the muscles were arhythmic, they were not purposeful, they were accompanied by paroxysms of intensity, but with no free periods. There was, however, no history of epilepsy, and some writers would no doubt classify the case as one of generalized tic.

A Case for Diagnosis.—This was presented by Dr. B. Sachs. The patient was a man, aged thirty-five years, who first came under the speaker's observation in 1897. He was a machinist by occupation. He had never come in contact with metallic poisons, and gave no history of gonorrhea or syphilis. He first noticed that pulling the left half of his mustache caused him no pain, while pulling the opposite half gave rise to the usual sensation. Subsequently, he had a carbuncle on the left side of the lip, which was opened without causing him any pain. Thorough and repeated examinations revealed nothing excepting a dissociated sensation in the distribution of the left trigeminal nerve. During the first year there was only a loss of pain and temperature sense in the greater part of the three branches of the nerve, with subsequent loss of sensation of the left cornea, and more recently, atrophy of the left masseter muscle. During his last examination of the patient, Dr. Sachs said, he noticed a slight involvement of the middle branch of the right trigeminus. There was no dissociation of sensation in other parts of the body, and no evidences of systemic or other disease. The knee-jerks were normal. Dr. Sachs said he had seen two cases similar to this one, in which the only symptom consisted of a dissociated sensation of the trigeminal nerve. One explanation he had to offer was that it was an unusual case of syringomyelia, in which the cavity formation was in the pons and not in the spinal cord. This he regarded as a rather venturesome diagnosis, because in such a case, in all probability, some of the other cranial nerves would have become involved after so many years. Another and more likely explanation was that the case was one of primary degeneration of the nerve, perhaps fibroid in character, such as had been described as occurring in nerves in other regions. Whether it would be proper to call it a neuritis or not he did not know.

Dr. George W. Jacoby said, that one of the things to be considered in connection with the case shown by Dr. Sachs was beginning tabes. The speaker reported a case of undoubted tabes that had been under his observation during the past eighteen years; in which the first symptom was an analgesia in the distribution of the middle branch of the trigeminal; there was not a dissociation of sensation, simply a reduction, which gradually became complete, and this persisted for five or six years before any other symptoms of tabes manifested themselves. In that case, Dr. Jacoby said, antisyphilitic remedies were given from the very onset of the analgesia, and persisted in for a long time, without exerting the slightest influence upon the subsequent development of the tabes.

Dr. William M. Leszynsky called attention to the decided atrophy of the muscles in the case shown by Dr. Sachs. The speaker said he saw no reason why the dissociated sensation should necessarily indicate the presence of syringomyelia. Dissociated sensation was occasionally seen in other conditions affecting the peripheral nerves.

Dr. Joseph Collins said, that while cases of tabes like the one described by Dr. Jacoby were very uncommon, they were occasionally met with, and he

had recently seen one come to autopsy, after twelve years' observation. In those cases, however, there was no pronounced muscular atrophy, which was such a conspicuous feature in Dr. Sachs's case, constituting, practically, a facial hemiatrophy. The more or less uninterrupted quivering or flickering of the muscles, particularly the masseter, as well as the distribution and course of the affection, militated against a peripheral trigeminal lesion. Dr. Collins said he was inclined to regard the case as one of central syringomyelia.

Progressive Muscular Atrophy.—Dr. L. Pierce Clark said, that cases of progressive muscular atrophy had been reported which were similar to the case shown by Dr. Sachs. In those cases the skin itself was not involved to the extent that it was in facial hemiatrophy. The case might be one of progressive muscular atrophy, with sensory changes due to degeneration of the sensory root.

Dr. Sachs, in closing, said he did not think the case had any features in common with ordinary facial hemiatrophy. For a period of five years, this patient only presented sensory symptoms. The apparent atrophy was due to wasting of the muscles supplied by the motor branch of the trigeminus. The quivering of the muscles, to which Dr. Collins had called attention, was more apparent than usual, and was probably due to temporary nervousness. The speaker said he had kept the possibility of early tabes in mind, but had found no evidences of that disease.

Dementia Præcox.—Has the recognition of dementia præcox advanced our conceptions of the various forms of mental derangement occurring in the adolescent period? Is not the present tendency to give too grave a prognosis in the youthful insanities? How frequently does dementia follow the mental derangements of early life?—Dr. B. Sachs, in opening the discussion of this subject, emphasized the fact that some cases correspond accurately to the types of dementia præcox described by Kräpelin and his followers. This was particularly true of the earlier forms of mental derangement occurring in members of families in which there was a very marked psychic taint, but even in these, many years might pass before an appreciable dementia sets in. The term dementia præcox, he thought, should be carefully restricted to such cases in which mental deterioration, at an early stage of the disease, was clearly recognizable, and should not be applied to those in which a dementia might set in in the far-distant future. The diagnosis of dementia præcox placed the stamp of an uncurable malady upon persons who might be sufficiently alert to be useful to themselves and to others for a long term of years, and in that sense did them distinct injustice. There seemed to be little gained in grouping widely differing cases under one heading. The older plan of clinical subdivision was more commendable, and the tendency to dementia should be insisted on only when there was reason to think that a deterioration was certain to develop at a relatively early period.

Dr. Adolf Meyer said, that the question under discussion was a very broad one. Largely through the influence of Kräpelin's earlier writings, the speaker said he had come to regard katatonia and hebephernia as degenerative conditions, and he was greatly surprised to see, in the fifth edition of Kräpelin's book, that the writer had apparently entirely changed his views on the subject, and had completely eliminated the degenerative features of those psychoses. Indeed, the very mention of degeneration to members of the Heidelberg school in 1896, when this great change took place, was looked upon as a sort of heresy. Instead of regarding these diseases of a degenerative origin, it was stated that they might befall anybody, just as general paralysis might befall anybody, and that they tended to end in dementia. Dr. Meyer said, he had always been inclined to believe that Kräpelin's rather sudden change of views was due to controversial reasons rather than to an actual conviction. The chief advantage that had been gained by Kräpelin's writings was that it had induced psychiatrists to break away from the old tradition of classifying all forms of insanity into melancholia, mania and paranoia, thereby neglecting many well-marked and striking forms of mental disease which could be readily recognized. Undoubtedly, Kräpelin went too far, a fact that he himself admitted when he said that the entire group was only classified provisionally, and would have to be still further subdivided. Kräpelin's description of dementia præcox was, on the whole, remarkably clear, and he was very painstaking in making the diagnosis. In a given case, all the symptoms might not be present, yet the patient might show some evidences of deterioration. Such cases might be regarded as allied to dementia præcox if the symptoms pointed sufficiently in that direction.

Dr. William Hirsch said, it seemed to him that this controversy concerning dementia præcox, as well as some other modern diseases, was largely a controversy about names. If it were not for the name dementia præcox, such a discussion would be practically unnecessary. The term did not originate with Kräpelin, but was used by Pick, of Prague, fully thirty years before, to describe a condition very similar to that to which it had been applied by Kräpelin. The clinical picture of dementia præcox is so broad that near every juvenile case of insanity would fit into one of the various categories, and the question arises whether there is really one important feature which all these cases have in common. Dr. Hirsch said they surely had nothing in common in symptomatology, because the clinical picture was too broad. Was the dementia a common feature of dementia præcox? Personally, the speaker said, his experience coincided with that of Dr. Sachs. He could not convince himself that all juvenile psychoses, whether of the katatonic or other types, would terminate in dementia. There was one feature, however, that was common to all these cases of acute juvenile psychosis, namely, that they all occurred on a degenerative basis. "We would always draw the conclusion that we had not to deal with a normal individual. These juvenile psychoses only occurred in individuals with inferior mental powers, and this fact should always be borne in mind in connection with the prognosis. Such a person might return to his relatively normal state, that is, to the condition he was in before the onset of the attack, which was never an absolutely normal condition. The fact was often lost sight of that these people never had a normal mind, but taking that for granted, it went without saying that any acute mental disease might intensify this mental inferiority, and that the patient might be worse off than he was before. Even if very decided dementia was present during the acute stage of the attack, it would not necessarily be a permanent condition; the patient might recover from this dementia and regain his relatively normal condition. The impaired mental condition of these pa-

tients, Dr. Hirsch said, did not necessarily imply a lack of intelligence, but might be characterized by hypochondriasis, by a lack of mental equilibrium or by morbid impulses.

Dr. Emmet C. Dent said, that a recent anaylsis of the statistics at the Manhattan State Hospital for the past year showed that out of 911 patients admitted, 290, or about 31 per cent., were cases of dementia præcox. The speaker said, that after serveral years' study of Kräpelin's theory, he was still inclined to believe that it was premature to discuss it. The group of cases included under the term dementia præcox was a large one, and in the course of time more appropriate names would doubtless be found under which the various types could be classified. A case of dementia præcox, when properly defined, was just as distinct a type as depressive insanity.

Dr. T. P. Prout said, that five or six years ago he made some examinations of the blood in cases of so-called dementia præcox, and found that the results he obtained were very variable. In some of the typical cases, during the early stage, there was marked leucocytosis, while in others the number of leucocytes was decidedly diminished. A similar discrepancy was noticed in the differential count. It therefore seemed to him that different types of mental disease were embodied under this head.

Dr. Allen Ross Diefendorf, of Middletown, Conn., said that melancholia was recognized as a psychosis of involution, while dementia præcox was one of adolescence, and he could see no close relationship between the two. The symptoms of melancholia, as at present understood, were well defined, and it could be safely said that the condition was very rarely encountered during the period of adolescence. A review of about one-half the cases admitted to the Connecticut Hospital for the Insane during the past five years, showed about 184 cases of dementia precox. A subsequent review of those cases showed that twelve were mistaken for melancholia. Of these, seven were of katatonic type, or were later recognized as katatonia, and five as hebephrenia. The speaker thought there was very little danger of confounding melancholia with dementia præcox.

Dr. Joseph Collins said, he did not agree with Dr. Sachs that the modern psychiatrist showed a tendency to make the diagnosis of dementia præcox with alarming frequency, nor did he agree with Dr. Hirsch that there was anything typical in the clinical picture of this psychosis, or anything in common between the various types of the affection, as described by their originator. Furthermore, he did not think that Kräpelin maintained that position. In his study of that writer's work, he could recall no ground for the statement that all these cases occurred on a degenerative basis. On the contrary, Kräpelin maintained that dementia præcox was a disease that occurred in individuals who were apparently sound, and that it was due to an auto-intoxication.

Dr. Edward D. Fisher said, he was inclined to think that Kräpelin allowed a wide latitude in his differential diagnosis of dementia præcox, and that his cases were rather younger than those cited by Dr. Sachs. For example, take an apparently normal individual of fourteen, sixteen or eighteen years, who suddenly, with or without psychosis, may show himself unfit for the work he is doing at the time, and is never able to take care of himself after that. We may have here a type of dementia which may never reach an extreme degree, that is, never go on to amentia. Such cases, Dr. Fisher thought, represented a large class to which Kräpelin referred in his writings.

Dr. Dent, in reply to a question, said that the cases of dementia præcox he has seen ranged in age from fourteen to twenty-five years. The average age was about twenty years.

Dr. Sachs, in closing, said that the figures quoted by Dr. Dent showed that a large proportion of the patients at the Manhattan State Hospital were being admitted under the diagnosis of dementia præcox, and he questioned whether many of those cases had gone on to a condition of complete dementia. The only point he wished to make was to throw a little doubt upon the extremely grave prognosis that had been given in this class of psychoses in recent years under the teachings of Kräpelin.

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, held at Oxford, England, July 26, 27, 28 and 29, 1904.

SECTION ON TROPICAL MEDICINE.—*Continued.*

(Continued from Page 855.)

Leishman-Donovan Bodies.—These parasites were discussed by a number of the members of the Section on Pathology. Dr. W. B. Leishman, of London, first took up the main facts known about these bodies. Since first observed a large number of observers have written concerning them. Donovan, Marchand and Ledingham, Manson and Low, Bentley, Rogers, and others have observed them, and it is becoming more and more evident that the disease associated with their presence is by no means uncommon in tropical countries, and there can be little doubt that, as the parasites themselves and the methods necessary for their demonstration become better known, more will be learned concerning them. Cases have been reported from countries so widely apart that it would be rash at this stage to attempt to assign geographical limits to the disease. The first case in which the parasites were found was that of a soldier, invalided from Dum-Dum in 1900 with tropical cachexia and splenomegaly, and soldiers at Netley presenting a similar clinical picture were so frequently found to have served in or near this station that he termed the condition "Dum-Dum fever." Such a name was, however, only intended as a temporary expedient for the avoidance of a periphrasis in speaking of the condition with which the bodies were associated, and, as it appears likely that the disease may prove to be identical with kala-azar, this well-known name will probably be adopted. Up to the present moment cases have been reported from three or four widely separated districts of India, from China, Tunis, Algiers, Arabia and Egypt. As knowledge of these endemic areas is added to, it would be of great interest to endeavor to find out any physical peculiarities they may possess in common, as this may help in the search for the alternative host which the analogy of malaria and other protozoal diseases would suggest to be necessary.

Distribution of the Parasites in the Body.—Originally found in the spleen, the parasites have since been met with in the liver, the mesenteric glands, the bone marrow, the kidney, and in ulcers involving the intestinal mucosa. The great majority of those who have searched for them in the peripheral blood have failed to detect them, but M. Laveran is of the opinion that certain small bodies occurring in the red

corpuscles in some of his specimens are young forms of the parasite. The most exhaustive accounts of the distribution of the parasites are those of Marchand and Ledingham and of Christophers, and their results are in many respects in marked agreement. According to these and other observers the parasites appear to be chiefly, if not solely, intra-cellular, and are met with in the protoplasm of large mononuclear cells, which are probably, as Christophers suggests, "macrophages," and of the same nature as those large phagocytes which, in malarial cases, are filled with ingested melanin granules. A fact which had been noted, and which appears to be significant, is that neither the parasites nor the cells which harbor them appear to suffer from their mutual association. In specimens obtained by splenic or hepatic puncture during life the parasites are, however, usually found free or in groups of several members, and such free or agglomerated parasites are frequently seen to be embedded in a structureless matrix or stroma, straining grey or pale blue with Romanowsky's method. This stroma or matrix is of importance, as it is largely owing to the different conceptions as to its origin that different views have been taken as to the nature of the parasite. That the true origin of this stroma lies in the disintegration of those large mononuclear cells through mechanical violence, and that the stroma represents a fragment of the protoplasm of one of those host cells, appears probable from the work of Christophers and of Marchand.

Symptomatology.—(1) Splenic and hepatic enlargement—the former being apparently constant, while the latter is common but not invariable. (2) A peculiar earthy pallor of the skin, and, in the advanced stages, an intense degree of emaciation and muscular atrophy. (3) A long-continued irregularly remittent fever, of no definite type, lasting frequently for many months, with or without remissions. (4) Hemorrhages, such as epistaxis, bleeding from the gums, subcutaneous hemorrhages or purpuric eruptions. (5) Transitory edemas of various regions or of the limbs. (6) Complications, such as congestion of the lungs, diarrhea and dysentery, have been frequently reported, and are occasionally the immediate cause of death. (7) Blood count. The cases coming under his own notice have shown a marked mononuclear increase, an interesting point, if confirmed by further experience, in view of the proved absence of malaria. To these positive signs may be added certain negative ones of hardly less importance: First, the absence of malaria, except as a concurrent affection, which yields to appropriate treatment; secondly, the negative result of the agglutination test to typhoid and Malta fever; and, thirdly, the resistance to medication, and especially to quinine—at all events, in the later stages of the disease.

Relation to Kala-azar.—It will be noticed that the symptoms detailed are very similar to those of kala-azar, a disease which has furnished matter for discussion at previous meetings of this Section, and concerning whose causation great differences of opinion have existed. He had suggested in his original communication that search should be made for these bodies in kala-azar, and Bently has since reported finding them in the spleen in cases of this disease, while his results have been confirmed more recently by Rogers. It is, perhaps, too early to say definitely that they are the cause of kala-azar, but it certainly looks as though this were the case, as they seem to occur constantly in this disease. If it should be so, the question arises whether the other cases in which the parasites have been found are identical with the kala-azar, and, if this identity is proved, we must then admit that the geographical distribution of kala-azar is much wider than has been supposed, and, further, that it is not uncommon amongst Europeans.

The Nature of the Parasite.—On this point, so important for the solution of many of the unsolved problems in connection with the disease, there has been a divergence of opinion, and it is much to be hoped that the question will soon be definitely settled. When it is, analogy should help us in clearing up the rest of the life history of the parasite, and put us on the track to what should be our ultimate goal—the prevention and, if possible, the stamping out of the disease. Stated briefly, the views that have been enunciated are the following: (1) Major Ross, working with films sent to him by Donovan, came to the conclusion that the bodies represented a new genus, belonging to the sporozoa, which he did me the honor to name Leishmania. (2) M. Laveran, also working with films from Donovan's cases, pronounced the bodies to belong to the piroplasmata, and gave them the name *Piroplasma Donovani.* (3) In his own opinion they appeared to represent a stage in the life-history of a flagellate organism, closely resembling a *Trypanosoma,* if not actually belonging to that genus. A few of those who have recorded cases of the disease have expressed their views upon this question of their nature, but Marchand and Ledingham, as a result of the study of their case, have come to the same conclusion as myself. To examine these views more in detail;—first, M. Laveran's view, that they are a species of *Piroplasma*—A parasite of the red blood corpuscles—has met with little support from other observers, whose most careful search has failed to demonstrate their presence in the red cells of the peripheral circulation, while, further, it has been pointed out that the arrangement of the chromatin, the method of apparent multiplication, and the tendency to occur in the protoplasm of the large mononuclear cells of the spleen and liver further militate against this theory. Such high authorities as Manson, Ross, and Marchand have also pronounced against this view. When the parasites are very numerous in a film it must happen at times that some are superimposed on the red cells, and when this occurs it is no easy matter to say whether it is a case of a true inclusion or not. But, in addition, Laveran has found pyriform bodies recalling the shape of *Piroplasma bigeminum* and he further regards the pale, grey-staining stroma, frequently seen surrounding the bodies, as representing the degenerated remains of the red corpuscle which harbored the parasite. A more probable explanation of this stroma appears to be that of Christophers. In a later publication Laveran reports that he has met with small intracorpuscular bodies in some of Donovan's films, taken from the peripheral blood of patients in whose spleens the parasites had been detected by spleno-puncture. These bodies Laveran considers as young forms of the *Piroplasma,* and he mentions a series of points in which they appeared to him to differ from young malarial parasites. This observation has not yet been confirmed.

Secondly, in Major Ross's view one has to deal with a representative of a new genus of the sporozoa, and he regarded "the individual bodies as spores

produced in the matrices, which would appear to be relics of the parent organism." In this connection it may be noted that the parasites found by Wright in a Delhi boil, may appear to be either identical or very closely related to the spleen bodies, are also regarded by him as belonging to a new genus, to which he has given the name "*Helcosoma.*" His own view is that the new bodies represent a stage in the development either of a *Trypanosoma* or of some closely-allied member of the *Flagellata.* Marchand and Ledingham endorsed this close resemblance, and also supported the deduction based upon it. Schaudinn, in following the various transformations undergone by a blood parasite of the stone owl when taken into the stomach of a mosquito (*Culex pipiens*), comes to the conclusion that this *Halteridium* is in reality a sexual form of a true trypanosome, to which he gives the name *Trypanosoma noctuae.* Again, Prowazek, working on similar lines to those of Schaudinn with a parasite of the house fly—*Herpetomonos muscæ domesticæ*—finds similar trypanosomal forms which also assume resting forms in much the same manner as *Trypanosoma noctuæ.*

From the descriptions and figures given by Schaudinn and Prowazek of these resting forms of trypanosomata, a very close resemblance may, he thinks, be traced between them and the new bodies, and in this resemblance lies the possible explanation of the flagellate origin of the bodies spoken of.

Elimination.—A fact of great importance in connection with the possible means by which the parasites are eliminated from the system is the presence of the bodies in the ulcers of the intestinal mucosa. This fact was brought out by Christophers and also by Manson and Low, and, from the frequency with which dysenteric complications have been reported in the course of the disease, it seems probable that this ulceration is a fairly constant feature. The parasites have not yet been found in the urine, but, as their presence in small numbers in the kidney has been noted, this is a possibility not to be overlooked. With regard to the discovery of Wright, already alluded to, that very similar parasitic bodies are met with in the well-known Delhi boil, it is obviously of the first importance that the identity or non-identity of those parasitic bodies with the splenic bodies should be established, and it is possible that the cercomonads which Ross found in these boils may be developed from, or may develop into, these bodies.

Cachexial Fever and the Leishman-Donovan Bodies.—Dr. Leonard Rogers, of Calcutta, presented a highly interesting paper on this subject. In a previous paper on cachexial fever he had found the parasites originally found by Cunningham in the Delhi boil many years previously, and a series of observations with examination of the blood from splenic punctures has shown him the probable identity of cachexial fever and the new parasites.

Races Attacked.—The great majority of the patients at the Medical College are natives, and my cases include Hindus, Mohammedans, Chinamen and Burmese women, and also two Europeans. Several of them had first been attacked with the fever while living in Calcutta. In addition to these he had found the parasite in the spleens of four cases in the European General Hospital, two being adults and two children, while several other similar cases clinically are under observation there, so that Europeans not infrequently suffer from the disease. Further, the disease frequently attacks more than one member of a family even among Europeans, a father and child having died of the disease, both with cancrum oris, in the European Hospital recently, while at the present time a mother and son are suffering from the disease there, in both of whom the parasite was found by spleen puncture. This, he pointed out in his original report, was the most characteristic feature of the distribution of kala-azar cases, in which it was the rule rather than the exception in hospital cases for at least half the household to have died of the disease. A similar, although much less marked, tendency is also present in the endemic form.

Cultivation of the Protozoal Parasite.—The recent cultivation of *Trypanosoma* has led him to try to obtain similar results with the parasites of cachexial fever by means of adding the blood obtained by spleen puncture to a small quantity of sterile citrate or soda solution, to prevent the blood clotting, and then keeping it under different conditions. Although when the solutions were kept at blood heat the parasites very rapidly degenerated and disappeared, yet when placed in a cold incubator at 27° C. and films made daily, they retained their natural conditions for several days and stained perfectly. Moreover, they increased markedly in numbers, so that in some instances, instead of two or three in a field of an oil immersion lens, as in the freshly-taken blood, after a day or two scores, and even a hundred, very young forms could be found in the same area. Further, very numerous dividing forms were found, even in a single field, although in the original specimens these were very few and far between, and required much searching in specially good specimens to enable even a few to be found, while in my experience the very young forms, which were so numerous in the cultures, are very rarely met with in fresh spleen-puncture blood, and then only within large cells, and not free in a gelatinous zooglea mass as in the cultures. These multiple forms result from the repeated subdivision of the nuclei of the ordinary oval form, as described in my former paper. In addition to this method of division, another frequent manner is a single division of both nuclei, followed by the splitting up of the parasite into two, the separation usually beginning from one end. The profession then has clear evidence of the survival and multiplication of the organism outside the body. As at a temperature of 27° C. the parasites only lived for three or four days, he next reduced the temperature of the cold incubator to 22° C. This temperature he found to be more suitable to the parasites, as they multiplied more readily, and when very few at first, several could easily be found in a field after a day or two. Further, he noticed that many forms of a considerably larger size than he had seen in fresh blood films appeared in a single day. This caused him to look out for flagellated bodies, for on first finding the spleen parasites in Dinajpur he was struck by the resemblance of the double nuclei, one larger than the other, with those of *Trypanosoma*, as Major Leishman had been before. Within the last few days in two of his cultures unmistakable *Trypanosoma* have appeared, together with smaller pear-shaped-flagellated bodies like those described by Plimmer in tsetse fly disease and other intermediate forms. The most marked of these cases (from which the illustrations have been taken) showed completely developed *Trypanosoma* with thick flaggella, macro-nucleus and micro-nucleus after incubation for one day, while the living forms were also seen in the blood culture moving rapidly among the corpuscles. They were quite numerous, and could readily be found after only a short search in a stained film, as will be seen from the specimen sent. This case was a typical one of cachexial fever in a Chinaman, whose spleen blood before incubation showed only fairly numerous

oval forms described by Leishman. This case had also been in hospital for fever two and a half months before, at which time he also found a few typical oval parasites by spleen puncture. The other case in which the trypanosomes have developed was by good fortune a case of kala-azar from Assam, from whom his assistant, Assistant Surgeon G. C. Chatterjee, kindly got some blood by spleen puncture, and after incubating for five days at 22° C. were found in the citrated blood a number of intermediate forms and a few full-developed trypanosomes. The fully formed trypanosome has, therefore, been already found in his cultures in both the endemic cachexial fever of Lower Bengal and also in the epidemic form of Assam, known as kala-azar, and the true nature of the organism is at least clear, Major Leishman's original hypothesis that the bodies he found were degenerate trypanosomes not being very far from the truth, as they must now be looked on as one stage of the epidemic went, than those whose temperature found by him.

Treatment.—Quinine has been unavailing. Segregation alone has resulted in any measure of success from the prophylactic side.

Piroplasmosis.—Major C. Donovan, of Madras, contributed to the discussion, basing his remarks on the observations of 72 cases of this old type of disease of supposedly newly discovered etiology. He proposes the name Piorplasmosis, believing that Laveran is correct in assigning the parasite to the genus *Piroplasma*. The clinical description of the disease was dwelt upon at length.

Notes in Kala-Azar.—Dr. Chas. A. Bentley, of Tezpur, Assam, read this paper. His conclusions were as follows:

It appears that the clinical history and the epidemiology of kala-azar gives certain indications as to necessary lines of research. It has been my experience during the four years during which he had been familiar with the disease that cases suffering from severe fever appeared to be more dangerous, as far as the spread of the epidemic want, than those whose temperature was more frequently near the normal.

It is these cases with high and continued fever who show on splenic puncture a larger proportion of fission and conjugation forms than the milder type of case. Again he had frequently noticed when the epidemic was at its height that cases which showed dysenteric symptoms, and especially those who became bedridden while suffering from dysentery, were sure to be followed by fresh cases in the same household or among the attendants. When the intestinal form of the disease is in abeyance, the epidemic gradually assumes a milder type, with a corresponding decrease in the case mortality. Another fact which appears to him to be of importance in regard to any investigation of the disease, is the comparative immunity of Europeans. Although isolated cases are met with in Europeans, they are uncommon. This fact appears to indicate that certain conditions are necessary for the spread of the disease, to which Europeans as a class are rarely exposed; and therefore the careful study of the case history of such patients when they are met with may be expected to give a valuable indication regarding the source of infection.

Tropical Splenomegaly and Oriental Sore.—Lieutenant S. R. Christophers said that whoever may have first seen the parasitic bodies variously known as the Leishman-Donovan bodies — *Piroplasma Donovani*, *Leishmania*, or *Helcosoma*—it is undoubtedly chiefly owing to the researches of Donovan that the occurrence of an entirely new parasitic disease of man was first brought to the attention of parasitologists and students of tropical medicine generally. With Donovan's discovery of the disease in Madras and Laveran's definite announcement of the parasitic nature of the bodies, speculation at once became rife regarding their zoological position, life-history and method of transmission. The earliest researches centered chiefly around the morphology and the zoological affinities of the bodies. They were thought by Leishman to be flagellates, on account of the conspicuous chromatin masses, which certainly appear to represent a karyosome and centrosome very like those of the trypanosomata. But that they are any form of degenerated tryphanosome is exceedingly unlikely in the face of the large number of recorded cases in which no trypanosomes have been present. The same unlikelihood pertains to their supposed affinities with the genus *Piroplasma*, and the discovery by Wright of the bodies crowded in the cells of granulation tissue in tropical ulcer would appear to be the final death-blow to this view. It has been suggested that the bodies are of the nature of micro-sporidia, but the proof for this rests on no further evidence than their remarkable uniformity in size and appearance. On the data we have at our disposal, it is indeed impossible to place these bodies in any of the genera or better known divisions of the sporozoa. A good deal of speculation has raged around the nature of the so-called "matrix" of Ross, "zooglea mass" of Manson, and "red corpuscle" of Laveran. In his first report he gave reasons for considering this nothing more or less than the cytoplasm of endothelial cells of the spleen, more especially that derived from the large macrophages which bud and vacuolate so as to give rise to the curiously definite masses in question. The process is much increased by the fluid usually present in the barrel or needle of the syringe used for puncture. A study of sections shows very clearly the real condition, which is one of endothelial cells gorged with the parasites. In regard to the nature of the infective process, it has very generally been taken for granted that the recently discovered parasite is a blood parasite, much in the sense that the malarial parasite is. If Laveran should be right in his surmise that the parasite is a species of *Piroplasma*, this will, of course, be true. As matters stand at present, the parasite does not appear to be related to this genus or to be a parasite at any time of the red cell. Are they to be considered as parasites of the plasma? On this point he has no hesitation in saying from the result of his recent researches that they are probably a blood parasite in no other sense than are the organisms of septicemic infection or the tubercle bacillus. While the attention of many observers was still directed to the novelty of the presence of the bodies in the spleen and liver of cases of tropical splenomegaly, Wright, in America, had, apparently independently, discovered the same bodies in large numbers in the granulation tissue of tropical ulcer, a lesion which had long been recognized as probably a specific local granuloma. That the bodies described by Wright are identical with those found in cases of enlarged spleen in Madras cannot be doubted after a study of the excellent photographs which accompany his paper. We also have the important communication from Captain James, that abundant forms indistinguishable from those in the Madras cases and in kala-azar from Assam were found by him in cases of oriental sore from North India. The general pathology of the lesion and the relation of the bodies to the tissues as described by Wright, makes it seem certain that in this case the newly discovered parasite is acting as the causal agent in a focal granuloma of the skin. Shortly after Wright's paper reached India, Donovan

found the characteristic bodies in small numbers in ulcers in an advanced case of the Madras disease with enlarged spleen and cachexia. Stimulated by the discoveries of Wright and Donovan, he examined very thoroughly the tissues of fatal cases of the disease, especially with reference to the skin and intestinal lesions found in such cases. The result has been to throw a considerable amount of light on the nature of the infective process. Bodies were found in the spleen, liver and bone marrow, intestine, lungs, testis and kidneys. In his first report he has already shown that the apparently free forms seen in specimens of splenic blood cannot be considered as other than forms artificially liberated by rupture of cells, more especially the large macrophages. The same relation holds good in the case of the liver and bone marrow, and in all three organs the condition may be described as an engorgement of the endothelial cells with the parasite. In the lung, testis and kidney, bodies were much less numerous, but were readily seen lying in cells of endothelial nature. Free forms were never seen in sections. In unulcerated papules of the skin, in small and large ulcers of the skin and of the intestine, the bodies were consistently present. They were as a rule scattered singly through the tissue, and appeared to be lying embedded in the cytoplasm of tissue cells. Closer investigation showed that they lay in the endothelial cells of the finest capillaries. No bodies were ever detected lying free in the lumen of vessels. In larger vessels, in the immediate neighborhood of granulation tissue, endothelial cells were seen containing from two to six bodies, and in many of the still larger ones cells crowded with bodies almost blocked the lumen. Briefly stated, in infection by the Leishman-Donovan bodies a type of infection exists in which the vascular endothelium is mainly implicated. The importance of such a fact is manifest. In the first place, it suggests the comparison of the Madras disease (chronic malarial cachexia) with the usual type of septicemia, in which, from the researches of Werigo and Kuhnan, it is evident infection of the blood stream with the septic organism is chiefly shown by the deposit of forms in the endothelium and leucocytes of the viscera. If, inded, we say that the disease seen in Madras is a systemic infection of septicemic type, we shall most nearly express what is known as to the nature of this new protozoan disease. This view will also allow us to see in oriental sore a local infection by the same organism. As regards the cycle of development of the parasite, multiplication of forms is mainly by binary fission, the larger fission forms being of secondary importance. The parasites having entered or been taken in by an endothelium cell, would appear to proliferate, causing eventually the disruption of the cell and the temporary setting free into the blood stream of the crowd of contained bodies. There does not appear to be any intracellular digestion of forms included in the endothelium cell, and this latter very probably constitutes a suitable host for the parasites, in spite of the fact that it may originally take them in by reason of its phagocytic properties.

Leishman-Donovan Bodies in Ceylon.—Dr. A. Castellani, of Florence, reports having found these bodies in patient, with tropical splenomegaly, in Ceylon, and Dr. Phillips, of Cairo, reports in finding them in Arabia and in Egypt.

Caution in Examination.—Sir Patrick Manson said that due precautions must be taken in the study of patients as the operation of splenic puncture is not free from danger.

Tsetse Flies.—E. A. Austin, of the British Museum, read an interesting paper on the varieties of the genus *Glossina*, or tsetse flies. Since these had come into so much prominence as carriers of *Trypanosoma* infection, they demanded more detailed study.

(To be Continued.)

BOOK REVIEWS.

Taylor on Genito-Urinary and Venereal Diseases and Syphilis. A Practical Treatise for Students and Practitioners. By Robert W. Taylor, A.M., M.D., Clinical Professor of Genito-Urinary Diseases in the College of Physicians and Surgeons, New York. New (3d) edition. Revised and enlarged. Lea Brothers & Company, Philadelphia and New York.

In presenting the third edition of this standard work on Diseases of the Genito-Urinary tract, the Venereal Diseases and Syphilis, the author has carefully revised, and in many places rewritten the text, which is profusely illustrated throughout with many new engravings and plates, both in color and monochrome. In order to keep abreast with the advance in this department, Dr. Taylor has added many new and instructive sections, thus bringing the book up to date in every detail, which undoubtedly makes it the most modern, and at the same time the most conservative and satisfactory guide both for the practitioner and student, and at the same time a valuable reference book for the specialist, containing, as it does, a thorough and systematic account of all that is recent and progressive in this special field of work. The sections devoted to diagnosis and treatment, both operative and non-operative, are so comprehensive, conservative and practical in every detail, that the physician who carefully reads them will be fully prepared to diagnose and treat this large and highly important class of cases in a scientific and thoroughly up-to-date manner.

The publishers are to be congratulated on the general appearance and make up of the book, which is far in advance of anything that has appeared on these subjects in recent years.

The Clinical Study of Blood Pressure. By Dr. Theodore C. Janeway, Lecturer of Medical Diagnosis, University and Bellevue Medical College. D. Appleton & Company, New York and London.

To have collected the immense mass of literature relative to the subject of blood pressure into one convenient and handy volume is the great service rendered by Dr. Janeway in this book.

He has classified the work under three heads, Physiological, Technical, and Clinical, giving a résumé of the important literature at the end of the book.

The author has abundantly shown the value of this information, and we cannot help feel that, for the first time, this important subject has been satisfactorily dealt with. The book is distinctly one worth having.

HEPATOPTOSIS COMPLICATED BY GASTROPTOSIS; A SUGGESTION AS TO TREATMENT.

BY ELLSWORTH ELIOT, JR., M.D.,
OF NEW YORK.

THE movement manifested by the various abdominal viscera may be either physiological or pathological. In the former instance, the degree of movement varies widely, being most pronounced in the hollow viscera, particularly in the alimentary canal, where it contributes largely to the proper performance of the functions of digestion and assimilation; it is least marked in the solid viscera where the movement referred to is largely respiratory, being due to the descent of the diaphragm.

In the hollow viscera the range of movement depends almost entirely upon the peritoneal relations of each individual organ, being most extensive in those organs supplied by a generous mesentery. On the other hand, in the solid viscera, the comparatively slight range of movement is explained by the absence of such a mesentery, as well as by the attachment of the viscus, at a point where it is not covered by peritoneum to the contiguous portion of the abdominal wall. Even in such an organ as the spleen, which is completely invested by peritoneum and is supplied by a mesentery, nature has evidently intended to curtail its movement, certainly in a downward direction, through the medium of the costocolic ligament.

The exercise of this movement, whether of hollow or solid viscus, does not affect the normal relation of the organ to the abdominal wall or to the contiguous viscera. At the conclusion of such a movement the quiescent viscus returns to that position in the abdominal cavity in which it properly belongs. On the other hand, when for any reason the normal relation is disturbed, such restitution may prove impossible, and the viscus once displaced may occupy an increasingly lower position in the abdominal cavity.

Such a condition may be due to various causes. In the first place, abnormal elongation of mesenteric attachment may occur, whenever, for any reason, the abdominal walls are unduly stretched, as in pregnancy, a fact which accounts for the prevalency of this condition in women.

Secondly, such abnormal range of movement and displacement may be due to the development of weakness in the extraperitoneal attachment of the viscus to the abdominal wall. Thus, in the case of the liver, the gradual diminution in the fatty tissue between the layers of the coronary ligament or in the case of the kidney, a similar decrease in the amount of perinephritic fat, predispose to downward displacement of these viscera.

Thirdly, a lack of tone in the viscus itself. This refers particularly to the hollow viscera. Here, when for any reason, the muscular tone of the affected organ becomes depreciated, either through disturbance of the general nutrition or from some irregularity in its nervous mechanism, a permanent displacement may occur.

Fourthly, gravity is a most potent factor in leading to displacement only when combined with one or more of the previous conditions. Under these circumstances an existing displacement is materially aggravated.

Such displacement may be limited to one organ or involve several simultaneously. Occasionally there is a general enteroptosis. In these cases weakness of the diaphragmatic attachment of the liver develops, and the consequent descent of that relatively heavy organ necessarily causes a downward displacement of all the abdominal viscera. It is not at all unlikely, that with the correction of the malposition of the liver the organs affected by its displacement, especially the right kidney and the stomach, right themselves without further treatment.

The symptoms associated with displacement of one or more viscera are very variable and may be divided into two general groups: (1) Those referable to the displacement of the individual viscus; (2) those of a reflex nature due to interference with the proper working of the abdominal nervous system. The former, not infrequently, absent, consist of local pain, together with symptoms indicating interference with the proper working of the organ involved. Thus, in case of the liver, attacks not unlike those of a typical biliary colic may occur, with or without moderate jaundice. In the stomach, nausea, loss of appetite, vomiting, evidences of defective gastric digestion with marked gastralgia very frequently develop. On the other hand, with the displacement of the kidney, symptoms due to the functional disturbance of that organ occur only when, from its malposition, mechanical interference with the outflow of urine results in intermittent hydronephrosis.

The latter group of symptoms, namely those due to reflex nervous disturbance, are usually well developed. The frequent occurrence of these symptoms in displacement of the uterus is very generally recognized. Similar symptoms of even more pronounced character and of wider distribution may be expected to occur in displacement of the abdominal viscera, for a larger number of nervous ganglia are affected, both by the pressure of the displaced organ and the tension to which the displacement subjects them.

The individual symptoms of this group are so well known that they require no special mention.

The objective symptoms may be elicited by direct examination. Thus the lower edge of the liver may be felt to extend a variable distance below the free border of the costal arch. The downward displacement of the stomach may be mapped out by percussion, after it has been inflated or partially distended with fluid. Analysis of stomach contents also gives valuable information. In nephroptosis, the kidney is readily felt by bimanual palpation, and the degree of excursion of its abnormal movement easily determined. The displacement of the solid viscera can always be recognized with greater facility after the patient has been walking, than if the patient has for some time previously been in the recumbent position.

The treatment is prophylactic and curative.

Prophylactic treatment includes all measures calculated to maintain the tonicity of both the abdominal wall and the abdominal viscera. Among the most important may be mentioned regular and suitable exercise, careful attention to the functions of digestion and assimilation, and in general the observing of a well-regulated hygienic habit of life. In women especially, where the persistence of weakness of the visceral ligaments after pregnancy is a part of a general subinvolution, should these precautions be observed.

The curative treatment is both medical and surgical. Medical treatment consists in the application of the general principles just enumerated together with local treatment directed to the displaced viscus. In case of displacement of the stomach, lavage, electricity with small doses of strychnine and arsenic to improve the tone of its muscle wall, are most likely to prove of service when that organ only is involved, and when the liver maintains its proper relation to the diaphragm. Similarly with the kidney, the generous exhibition of fats both in diet and by the administration of cod-liver oil may afford relief by increasing the general strength, as well as the strength of the fatty capsule of the affected organ. Again, however, the chances of a permanent cure are slight, if displacement of the liver exist, for the upper pole of the right kidney (the one usually affected) is in contact with the under surface of the liver, and any movement downward of that viscus must necessarily be transmitted to the kidney beneath. The descent of the kidney in these subjects may occasionally be checked by the wearing of a well-fitting pad.

In all these cases, particularly when nervous symptoms develop, general benefit is derived by continued rest in bed. By this means, gravity as an etiological factor, is eliminated, or may be even utilized to effect the return of the displaced organ to its proper position by raising the foot of the bed. This is especially true of the solid viscera. With the recovery of the patient recurrence is less likely if some occupation is selected that does not necessitate continued and protracted standing in the same position.

The surgical treatment varies according to the organ affected. The object of this paper is to call attention to a new method of operation in those cases where, with gastroptosis, there is a descent of the liver as well. Hitherto, with or without this complication, attempts have been made to relieve the gastroptosis by suture of the stomach to the anterior parietal peritoneum, and in a few cases by a reefing or shortening of the gastrohepatic omentum—attempts that have resulted in no material benefit to the patient. The chief objection to either of these methods seems to be that, when the liver descends, the weight of that organ continues to be exerted against the stomach and thereby interferes with its function as well as the function of the other viscera that are pressed down into the abdominal cavity. The object of the operation here suggested, is to anchor the liver so securely in its position that the displaced stomach and other abdominal viscera will be relieved of its superincumbent weight, and will then with or without general therapeutic measures return more or less completely to their normal position, with a corresponding improvement in their function.

The operation consists in the exposure of the liver and stomach through a median incision above the umbilicus. The obliterated umbilical vein, forming a thick cord in the free edge of the falciform ligament, is then identified and drawn forward until it comes in contact with the parietal peritoneum. The hepatic extremity of the ligament then rests against the under surface of the right lobe of the liver in front of the transverse fissure. The lower or umbilical extremity is in close contact with the anterior parietal peritoneum, the two portions of the ligament now forming a right angle. In this position the round ligament is sutured to the anterior parietal peritoneum with chromic gut and the redundant falciform peritoneal reflection is spread out laterally and sutured to the contiguous portion of the parietal peritoneum with the same material, in this way forming a species of shelf for the under surface of the liver. The abdominal wound is then closed in layers.

REPORT OF CASES.

Case I.—M. L., female. Admitted to the Presbyterian Hospital, March 23, 1904. Patient has always enjoyed good health until four weeks previously. At that time, without known cause, she developed pain in the epigastrium which was more marked on the right side, and which confined her to bed for one week. Ten days previous to admission the pain recurred and increased in severity, being especially severe for the past two days, and of a sharp, knife-like character. Four days before vomiting appeared, the vomitus consisting of the contents of the stomach, and after that the patient was unable to retain food of any kind. During this same time the bowels were

constipated. Two days previous patient became feverish and simultaneously jaundice appeared. On both days chills occurred. On admission, temperature was 104° F., the pulse 110. Shortly after admission the patient developed a severe chill, the temperature rising to 107° F., the pulse to 120.

On examination, the abdomen was flaccid and moderate tenderness and rigidity were elicited in the upper right quadrant near the border of the costal arch. There was also some rigidity of the corresponding portion of the arch. Extending a distance of two inches below the level of the umbilicus, the free edge of the right lobe of the liver could be felt. The urine was normal, save for a heavy trace of bile. There was a considerable amount of jaundice. There was a leucocytosis of 15,000, gradually decreasing and reaching normal at the end of a week, also a slight pharyngeal cough with a moderate whitish expectoration.

On the day of admission patient vomited after taking a little water, which was repeated later in the evening. On the day after admission, the temperature fell to 103.5° F., thereafter decreasing gradually day by day, reaching normal in about ten days. An enema was administered with a large brown result. There was no further vomiting.

Five days after admission, patient had a severe attack of tachycardia, the pulse reaching 250 (counted with the stethoscope over the apex), decreasing the following morning to 180 (with the administration of digitalis) and thereafter decreasing to normal. There was no corresponding rise in the temperature. With the subsidence of the attack of tachycardia, the general condition of the patient improved. The appetite improved, the bowels became less constipated, the jaundice decreased and then disappeared, and by successive examinations the edge of the liver was felt to rise above the level of the umbilicus, to a distance of about two inches below the costal arch. At the end of three weeks, the patient was allowed to sit up in a chair and shortly after to walk. A few days thereafter she was discharged from the hospital.

The patient has been examined at intervals of two weeks since her discharge. She has been able to do light housework and there has been no recurrence of any of her former symptoms. The edge of her liver has, however, returned to a position below the level of the umbilicus.

Case II.—M. P., forty-one years old, female. Admitted to the Presbyterian Hospital November 30, 1903. Patient has had three children and three miscarriages, the youngest child being now eight years old. Has always enjoyed excellent health. One year ago pain developed on the right side of the abdomen. This was increased on exertion and at times extended down the right leg, being so severe as to confine the patient to bed. For the last three months patient was unable to attend to household duties, and for the past six weeks vomiting after eating was frequent, intensifying the pain. During the same time she suffered from severe abdominal cramps with distention and has been unable to sleep. During the previous three months she lost much strength and forty-two pounds in weight. The chief complaints were pain, vomiting and general weakness.

Examination.—The abdomen was of average size, soft, of poor general tone and moderately distended. Stomach tympany extended below to within one and one-half inches of the crest of the ilium, crossing the median line one inch below the umbilicus, and the free border of the costal cartilage at the tenth rib. The lesser curvature crossed the epigastrium one inch below the ensiform and extended as high as the seventh rib in the left hypochondrium. The liver descended in the right hypochondrium a distance of two inches below the free border of the costal arch. A peristaltic wave could be seen at intervals passing from left to right just below the umbilicus. The stomach contained free hydrochloric acid both before and after operation. Prior to operation, examination of stomach contents showed many starch granules, fat globules, granular detritus and epithelial cells.

December 9.—Patient has been in bed since admission, with lavage and general tonic treatment without showing any improvement.

Operation. Gas and ether.—On opening the abdominal cavity, the liver was found to extend two inches below the free border of the costal arch, the greater curvature of the stomach to lie opposite the level of the umbilicus, the stomach itself to be moderately dilated. The stomach was sutured to the anterior parietal peritoneum on either side of the median line with two rows of chromic gut sutures, and after denudation of the opposed peritoneal surfaces of the liver and diaphragm, the round ligament was treated in the manner described in the earlier part of this paper. Complete closure of the abdominal wound followed.

There was very slight reaction, the wound running the ordinary course of those which heal primarily. The amount of postoperative vomiting was no more than that observed in the usual laparotomy. By the seventh day all discomfort after eating had disappeared, and the patient experienced no further abdominal pain or cramps. There was progressive improvement, and she was discharged at the end of four weeks, after she had been walking around the ward for a week without any return of her symptoms. To permit of the approximation of the denuded liver and diaphragmatic surfaces, the patient was kept in the Trendelenburg position for two weeks after the operation. Two months after operation patient had been attending to her household duties for some weeks. She experienced occasional slight pain after eating. She gained ten pounds after her discharge from the hospital. Six months after operation, the patient was mak-

ing daily trips of more than six miles between her residence and place of business. She continued to enjoy good health.

Case III.—M. K., thirty-eight years old, female. Admitted to the Presbyterian Hospital December 7, 1903. Patient had had two pregnancies, nine and seven years before. Eighteen years previously she had an attack of severe pain in the epigastrium, with jaundice, confining her to bed for three weeks. A similar attack occurred three years before admission with severe pain in the right hypochondrium, and vomiting. The jaundice persisted for a month. In November, 1900, a ventral fixation was performed by me at the Presbyterian Hospital. At that time there was retroflexion and some menstrual difficulty, which was relieved by the operation. April, 1903, the patient had an attack of fainting, with chills and fever, and severe pain in the back, but no vomiting or jaundice. Since then she has had frequent attacks of fainting, with abdominal pain, experienced after eating, and occasional jaundice. For several months past she has been unable to do any heavy work.

On examination, the wall of the abdomen was soft and retracted. The lower border of the liver could be felt two inches below the free costal margin. On bimanual examination, in the right lumbar region, the right kidney could be felt to be slightly movable.

Operation. Gas and ether.—On opening the abdominal cavity, the transverse fissure of the liver was found to be in close contact with the lesser curvature of the stomach. The greater curvature was opposite the umbilicus. The right kidney enjoyed an excursion of two inches during inspiration. The gall-bladder and ducts were normal. The liver was raised a distance of two inches by suture of the round ligament, and the abdominal wound was closed after denudation of the opposed peritoneal surfaces of the diaphragm and liver. Trendelenburg position.

There was no unusual nausea or vomiting. The bowels moved on the third day. The pain decreased and disappeared with steady improvement of the appetite. At the tenth day, slight pain in the back alone remained. The patient continued to improve and left the hospital in excellent condition. Six months after the operation, patient enjoyed very good health. There was occasional pain after eating and some obscure pain low down in the pelvis, but her general condition remained greatly improved.

These cases are of very considerable interest. In the first case, no operation was performed, the patient having always been well to within a short time of the original attack. Here conservative measures proved successful in relieving the attack, notwithstanding a very severe and unusual attack of tachycardia. It is interesting to note that, shortly after she had assumed the vertical position, the liver returned to the position that it occupied at the time of the patient's admission to the hospital and that this occurred without any return of the previous symptoms. Whether a relapse will occur or not is purely a matter of conjecture. Too short a time has elapsed to regard the patient as permanently cured.

In the second case the stomach symptoms were very sharply developed and the resulting loss of flesh and strength were as great as in any case of carcinoma. The patient desired to avoid an operation if possible, yet her condition became so deplorable, that finally she was eager for any procedure that might afford relief. The good effect of the operation might be said to have been almost instantaneons. After the subsidence of the discomfort that is observed after any laparotomy, she experienced almost complete relief and began to relish and assimilate food in considerable quantities. Whether in this case, the good result can be ascribed to the suture of the stomach or to the elevation of the liver, or simply to the rest in bed, is a matter of doubt. The total failure of gastrorrhaphy to afford even temporary relief in other cases of this description, together with the sudden change directly after the operation, when a week's rest in bed prior to the operation had not materially changed the patient's condition, seem to warrant the belief that the shortening of the round ligament was instrumental in effecting the noted improvement. In the third case, the symptoms rather pointed to some form of cholelithiasis, but the physical examination of the liver revealed its low position and the laparotomy made the diagnosis certain. Again, in this instance, the result at the expiration of six months may be regarded as satisfactory. It is also interesting to note, in this case, the examination of the uterus showed it to be firmly secured to the anterior abdominal wall by a mesial and anterior ligament about two inches square, the result of the prior ventral fixation.

In conclusion, the writer does not desire to belittle the importance of medical measures. These should be always carried out wherever it is possible, and only when the condition of the patient ceases to improve is it wise to resort to surgical treatment. The writer wishes also to still further emphasize the fact, that the method suggested must not be expected to afford relief in all cases and that the results in the cases herewith published six months after operation must not be regarded as final. The fact remains, however, that a very marked improvement was secured in the two cases treated by this method, and this improvement seems to warrant the early publication of this paper in order that others may be induced to try the same procedure. For it is only by that means that an accurate estimate of its true value can be obtained.

48 West Thirty-sixth Street.

Gifts to Mineola Hospital.—It has just been announced that Mrs. W. K. Vanderbilt, Jr., has given to the Hospital Association of the above institution $2,000, to be used for repairs. Mr. W. B. Leeds, another friend of the hospital, also recently gave $2,000.

RACES AND PEOPLES WITH REGARD TO TUBERCULOSIS.

BY JOHN B. HUBER, A.M., M.D.,
OF NEW YORK.

THE negro is exceedingly prone to consumption, which destroys every other adult among his people. It would seem, however, that this disease was unknown among the original blacks in Africa until within comparatively recent generations, when the exploring whites decided to confer upon them certain prearranged blessings of civilization. Their immunity was probably due to the fact that barbarism does not suffer the disadvantages of badly-ventilated, badly-drained houses, indoor life, factory work and like conditions of civilization upon which tuberculosis thrives.

Harris (*Journal American Medical Association*, October 3, 1903) declares that before the Civil War tuberculosis was almost unknown among the slaves; that it does not occur on the West Coast of Africa, except when it has been imported by the white race and acquired by the negroes living a semi-civilized life. Millard states: "I have excellent authority for saying that the disease is rare among the negroes in Africa, and in the interior is almost never known." Flick considers that the negro race in Africa was free from consumption until its members began to associate with other races.

No doubt tuberculosis has taken the same course among the negroes as did measles among the Fijis. Measles were entirely unknown among these people until some whites who came there introduced it. On account of this, the aboriginal inhabitants died off in enormous numbers of this disease, which is now comparatively innocuous among us—40,000 Fijis in a population of 150,000. This exemplifies the established fact that a given infection acquires an unusual malignancy when for the first time it invades a race previously immune. On the other hand, an infection tends to lose its virulence in the course of centuries, as with the Jews, who are singularly less prone than other races to tuberculosis (Billings, Korosi, Fishberg, Hoffman).

Flick considers that the history of consumption in all new countries into which it has been introduced, shows that it has had a rise, a climax and a decline in prevalency, citing the experience in the islands of Madeira and Bermuda, and the progress of the disease from east to west in the United States in illustration of his view. In New York City, from 1804 to 1820, the deaths from consumption were one in 4.2; from 1820 to 1835, one in 5.4; from 1835 to 1850, one in 6.5, and from 1848 to 1859, one in 8.4. In Rhode Island the percentage of deaths from consumption was in 1867, 20.74; in 1883, 15.03. The mortality statistics of the older States and cities show in the same way a progressive decrease; those of the newer States and the Territories show either a standstill or a decrease. "The avidity, however, with which the disease takes hold of new material illustrates its subservience to the law of acclimatization better even than its history in different countries. "It has decimated," declares Flick, "the natives of probably every island which has been colonized by England during the last few hundred years." The native-born African negroes have thus suffered terribly from it. In Egypt the negroes and Abyssinians are decimated by it. In Gibraltar, for twenty years the comparative deaths between whites and blacks have been, per 1,000: Whites, 6.1; blacks, 33.5. During the early American slave trade the proneness of the negro to consumption was noted by Rush and others.

Certain habits of the negro are certainly predisposing. I have been informed by our Consul at Nassau (New Providence) that it is a custom among the negroes in that region, no matter how hot the nights might be, to keep the doors and windows of their huts tightly closed, and to burn lamps or candles throughout the night, to keep the evil spirits out and to scare them away. Such superstitions as these are common also, I believe, among negroes in our Southern States. The negro, moreover, eats much pork, and swine are among the tuberculous animals. To say the least, this is an unhygienic diet for hot regions. The negro is said to be inordinately addicted to alcoholism; if so, this factor should predispose more than among the whites, for the same reason that obtains among the Indians, to whom we will presently refer.

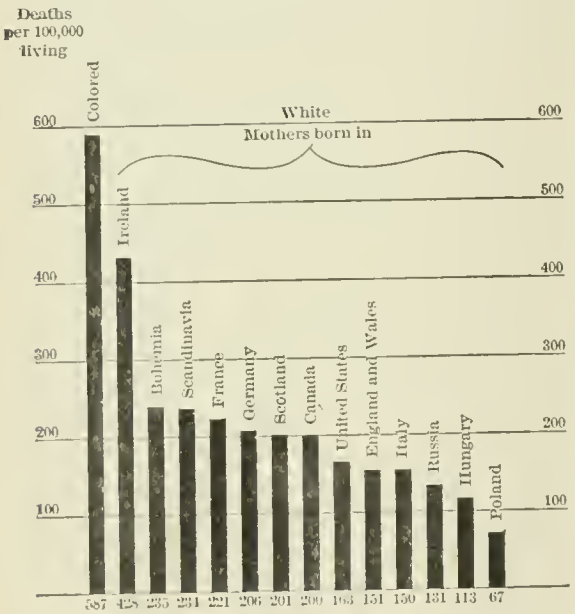
Coleman declares the negro to be ignorant of hygiene and adverse to water; that his food is often insufficient and unwholesome, and unsuited to the climate in which he lives; his clothing is unhealthful; he is shiftless and improvident. Syphilis and gonorrhea, by weakening his system, render him susceptible to tuberculosis. Many a negro now works indoors, and the houses in which he lives are overcrowded—unfortunate conditions, since the tendency of his race has been agricultural and toward out-of-door life.

Harris considers that the negro's small lung capacity, as compared with that of the white, and his deficient brain capacity render him less resistant to the disease when once acquired. Where the two races live together, three times as many negroes as whites die from tuberculosis. And Harris and Coleman both conclude that unless the hygienic and moral surroundings of the race are improved, there is danger of extinction.

It seems that the Indian was free from tuberculosis before his contact with the whites, living as he did in the open air and without alcohol. The "fire water" introduced by the white man (a most vicious, impure, cheap and harmful form of alcohol) has certainly been a large factor, all the more for the reason that the whites have, through many previous centuries, rendered themselves comparatively seasoned with regard to this stimulant, to which the Indian has not yet accustomed himself.

Rush stated, more than a century ago, that consumption was then unknown among the Indians of North America. Flick considers that prior to the advent of the white man—and especially the Englishman—consumption did not exist among the American Indians. Whenever England colonized the Indians took the disease, so that in the course of time it became even more prevalent among them than among the whites. The disease increased from east to west. John D. Hunter, Esq., who was for fifteen years a captive among the Indians, wrote in 1822: "I have known pulmonary consumption to occur among the Indians. It is rarely seen, however, except in those who are addicted to intemperance, and even in those cases it is by no means as common as among the whites. It is worthy of notice that their females are not as much subject to the disease as the males are."

In 1854 George B. Buckley reported that In-



dians east of the Rockies suffer from inflammation of the eyes and consumption. In 1870 Dr. Thomas Williams wrote of the Dacotas, of Minnesota, that "of those over ten years who die of disease, I think one-half die of consumption." It has almost exterminated some American tribes.

The death rate from consumption among Chinese in this country is, I believe, very high indeed. As regards New York City, their dreadfully unhygienic living, their sleeping in bunks, in vitiated atmospheres, their overcrowding, their addiction to opium and other enervating vices, and like circumstances abundantly explain their high mortality from tuberculosis.

Miss Lillian Brandt, to whom I am indebted for the accompanying diagram, has supplied some interesting data in the "Handbook on the Prevention of Consumption" of the Charity Organization Society. The high mortality among the Irish people is no doubt due to the inordinate alcoholism which obtains among their poor, their careless, improvident nature, their inheritance of poverty through many generations, and the overcrowding among them in our tenements.

The Bohemians come next, though a long way behind; their habit of congregating in cities, their unhealthful housing conditions, and their indoor occupations explain their mortality rate.

The Scandinavians are reputed a healthy race, and so no doubt they are at home. However the effect of new climatic conditions upon them, and the formation of a radically different physical type in the second generation may account for their comparatively high mortality in this country. Until we reach the Italians the conditions are such as prevail in civilization generally, and no observations are strictly pertinent in this place.

We would expect a higher mortality among the Italians, for their indoor life in this city is very unhealthful, they are exceedingly dirty and they are said to be much underfed. Moreover, being an ignorant and superstitious people, and no doubt fearing often the imaginary terrors connoted by registration, they are given to concealing their cases; so that by no means all are reported. This observation probably applies to many of the fifty odd tongues represented in New York City. Many Italians want to die in their fatherland; so that many cases no doubt leave for home before they become very bad indeed. Many poor Italians work in this country during the summer months and return to Italy in the fall. There are, for instance, many such transported in the steerage of the Netherlands-American steamship line. Besides the Italian's nature is sunny, not given to worry, and these people are largely engaged in outdoor work, peddling and upon public roads, etc.

The Hungarians, the Russians and the Poles in New York are mostly Jews. We observe that these peoples have the lowest death rate. It would seem that the Jewish race, here as elsewhere, suffers less from consumption than any other, except perhaps the Quakers. And this is all the more strange, because the Jewish race, in New York City at least, seems to be subject to pretty nearly every possible condition conducive to tuberculosis. I would attribute their low death rate, in large measure, to three main factors:

They are said to be a temperate people with regard to alcohol, which they take in moderation. The Jews are seldom drunk; "they have no drink problem." Again it would seem that the Jewish race has in the forty centuries of its existence established for itself a comparative immunity to this disease.

And lastly, there is their obedience to the Mosaic Laws regarding kosher food, which laws are, I understand, very faithfully obeyed by the poor Jews. The Jew would thus be not so likely to consume tuberculous food stuffs.

THE CONSUMPTION AND ELIMINATION OF WATER IN DRY AND MOIST CLIMATES, WITH SPECIAL REFERENCE TO THE CAUSE OF BRIGHT'S DISEASE.[1]

BY WILLIAM S. CARTER, M.D.,
OF GALVESTON, TEX.;
PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF TEXAS.

FOR a considerable time it has been felt by the physicians and people of Galveston that Bright's disease is more prevalent in this city than in most communities. The reports of the John Sealy Hospital of Galveston do not show the proportion of cases of Bright's disease in the medical wards, to be any greater than in the hospitals of other cities. A comparison of the mortality statistics, however, shows that there are more deaths from Bright's disease in proportion to the total number of deaths than in most cities, in spite of the fact that the mortality rate (per thousand of population) is remarkably low. With the exception of New York City, the percentage of deaths from this cause is nearly double that of most of the large cities in various parts of the country.

This condition is commonly attributed to climatic conditions—to the high degree of relative humidity, together with the long season of warm weather. Different theories have been advanced to explain how these conditions could possibly produce disease of the kidneys. Some contend that this atmospheric condition interferes with evaporation from the skin and throws greater work upon the kidneys; others hold that in the effort at heat regulation the sweat glands are more active, resulting in a concentration of the urine, which causes irritation of the kidneys and possibly interferes with renal excretion.

The observations presented in this paper were undertaken with the object of determining the influence of dry and moist climates upon the amount of water consumed, and the amount given off as urine, and whether or not there is any relation between the prevalence of Bright's disease and the climatic conditions.

The first observations were made by the writer upon himself over a period of six days in Boulder, Colorado, at an altitude of 5,400 feet above sea level, and these were contrasted with similar observations in Galveston at the sea level. The former observations were made in July; the latter in September. While the weather was a little warmer during the series in Galveston, the difference of temperature was not so great as the difference in humidity. No effort was made to take fluid at regular intervals or to take a uniform diet, but the natural inclinations were followed in this regard and the amount of fluid taken as a drink recorded. These were not added up until after the series was completed so that no mental factor could enter into the results in any way.

TABLE I.

Observations in Boulder, Colorado, July 17 to 22. Altitude 5,400 feet.

Number and date of observation.	Dry bulb thermometer, Fahrenheit.	Wet bulb thermometer, Fahrenheit.	Dew point.	Relative humidity (per cent.).	Barometric pressure (mm. Hg).	Amount of water as drink in c.c.	Amount of urine in c.c.	Sensible perspiration.	REMARKS.

					Average	1940	1404		

The conditions were very similar in regard to exercise, etc. Coffee was taken once a day, with breakfast—an average of 165 c.c. in Boulder and 300 c.c. in Galveston. If the difference in the amount of coffee consumed had any effect, it should have caused greater activity of the kidneys during the series of observations in Galveston. By strange coincidence the average of the six days in Boulder and that of the nine days in Galveston, show that exactly the same amount of urine (1,404 c.c.) was passed in both series. The average daily amount of water taken as drink was 2,140 c.c. in Galveston, while that in Boulder was 1,940. This means that the moisture given off by the lungs and skin in the moist climate exceeded that given off in this way in a dry climate by 200 c.c. From September 18 to 24, there was a Texas "norther," *i.e.* cool, dry breezes from the north prevailed and there was very little sensible perspiration as the weather

[1] Read before the Section on Pathology of the Texas State Medical Association, April 30, 1904.

was pleasant. During this time there was little difference between the water consumption and elimination in Galveston, as compared with that in Boulder. During the first and last days of the obesrvations in Galveston the weather was hot, sultry and uncomfortable, causing considerable sensible perspiration, and during these days more water was consumed and less was given off in the urine.

The observations of temperature, pressure and humidity were made in the middle of the forenoon and in the middle of the afternoon in the series in Boulder, and a mean of these is given in the table. Similar observations were made every three hours from 8 A.M. to 11 P.M. in the Galveston series, and an average of these is given in the tabulation.

These observations are open to the objections (1) that they were made upon a single individual, and (2) that there was not only a difference of humidity, but also a vast difference in atmospheric pressure, as Boulder is nearly one mile above sea-level, and the latter might influence the circulation and possibly metabolism. To overcome these objections arrangements were made to carry on observations simultaneously upon three men in good health in San Antonio, and also upon three healthy adults, besides the writer, in Galveston. These were made in September, 1903, and to compare the climatic conditions the officials of the United States Weather Bureau at both of the stations have very kindly furnished three daily observations as to temperature and humidity during this period. San Antonio is only about 700 feet above sea-level, and in general it may be said there is little difference in

Average.....	1064	2616	1245	2045	696	1956	899	1800

the mean temperature of these two cities. The chief difference is in the relative humidity and this is most marked at noon and in the evening. There is also a much greater difference between the maximum and the minimum temperatures in San Antonio than in Galveston.

As in the first series no effort was made to use a uniform diet or to take fluid at regular intervals, but the natural inclinations were followed and all fluid taken as drink was recorded. As the object of the observations was unknown to the physicians and pharmacists who kindly assisted me in making these observations, it can be said that the results were not affected in any way by any mental influence.

The subjoined tables show the climatic conditions and the amount of water consumed as drink and eliminated in the urine. The urine was collected for the day (7 A.M. to 7 P.M.) and night (7 P.M. to 7 A.M.) separately, and the specific gravity of the urine was taken in each case, but these details do not bear upon the results. The amount of urine passed during the day as compared with the amount passed during the night varies with different individuals but on the average the former only exceeded the latter by 30 c.c., notwithstanding the fact that the amount of water consumed during the day was from two to ten times greater than the amount of fluid taken as drink during the night period. On the average the specific gravity of the urine was the same for these two periods. It is evident that the excessive amount of water consumed during the day is given off by the skin.

A comparison of the average for seven days (September 15 to 21) shows that the average daily amount of fluid consumed in San Antonio was 1,734 c.c., and the average amount of urine given off was 1,218 c.c. The averages in Galveston for the same period were 2,126 c.c. of water as drink, and 1,016 c.c. of urine. The observations were continued for eleven days in Galveston, and an average for this period gives 2,140 c.c. of drink and 976 c.c. of urine.

These results show that the average daily amount of fluid consumed in Galveston was approximately 400 c.c. greater than that taken in San Antonio, while the quantity of urine was approximately 200 c.c. or 240 c.c. less. The use of coffee did not cause this difference, for more coffee was consumed by those in Galveston than by those in San Antonio. The average daily amount of coffee consumed was as follows: In Galveston, I. 320 c.c.; II, 310 c.c.; III, 380 c.c.; IV, 150 c.c. In San Antonio, A, none; B, 380 c.c.; C, 200 c.c. If the diuretic action of the coffee vitiated the results at all it was by giving too high an average for the daily amount of urine in the Galveston series.

These results confirm the first series of obser-

vations, and seem to justify *the conclusion that one takes more fluid as drink in a moist climate and passes less urine than in a dry climate.* Probably the amount of moisture given off by the skin and the lungs in dry climates is not so great as is often thought. The sensible perspiration which results from the effort at heat regulation on the part of the animal economy in a hot, moist climate, probably accounts for this difference.

The important question now arises, Has this anything to do with the causation of Bright's disease? This question cannot be answered by general impressions, or by comparing small numbers. Below will be found a comparison of the mortality records of different cities for the year 1900, taken from the United States Census Report, and of the climatic conditions, taken from the reports of the United States Weather Bureau. The percentage of relative humidity for the summer months is the average for the years 1900, 1901 and 1902. The temperature is the "normal temperature" for these cities and represents the average for about twenty years. The humidity of Galveston and San Antonio is also the average for sixteen or more years.

In the case of Galveston the total number of deaths from all causes and the proportion of deaths from Bright's disease are taken for a period of three years (1901 to 1903 inclusive), as this gives a longer period of time and a safer number for making comparisons. It is impossible to determine from the records of the Health Office the proportion of acute to chronic Bright's disease, or the proportion of parenchymatous and interstitial forms of the disease. The cause of death is often reported as "Bright's disease" or "uremia." The records of the John Sealy Hospital of this city, do not show an unusual proportion of acute Bright's disease, and the numbers of chronic parenchymatous and chronic interstitial forms, vary for different years, but do not appear to differ from those reported from other hospitals. It is the opinion of medical practitioners in Galveston that the disease is generally chronic, and seems to attack young people (under twenty or thirty years) with unusual frequency. In such cases it is usually

* Total number of deaths was 1441, but 147 deaths were due to tuberculosis in non residents and these were deducted.

parenchymatous degeneration primarily, with secondary interstitial changes, and often there are also late arterial changes. When the disease occurs in middle or advanced life, the interstitial form seems to be more frequent, and there is pronounced arteriosclerosis.

A careful study of the table, shows that there is no relation between the degree of humidity or length of the warm summer season, and the mortality from Bright's disease; nor does the latter bear any relation to the general mortality rate. For instance, in Denver and Boston, the conditions of temperature are very similar while there is a wide difference in the humidity, but the proportion of deaths from Bright's disease is practically the same. There is considerable difference between the relative humidity in Galveston and in San Antonio, and also in the proportion of deaths from Bright's disease, but, on the other hand, the mean humidity and temperature are very similar in New Orleans and Galveston, while the death rate from Bright's disease in the latter city is nearly double that of the former. Indeed, the mortality rate from Bright's disease in New Orleans does not differ from that in New York, Philadelphia, Baltimore, St. Louis, St. Paul and Minneapolis, although the climatic conditions are very different.

Doubtless there are errors of diagnosis in many obscure cases, and often the existence of Bright's disease is unrecognized, but these conditions exist in all communities and a comparison of statistics is the only means that we have of determining the unusual prevalence of a disease in any locality. There appears to be no doubt that Bright's disease is more prevalent in Galveston than in most cities, but it seems highly improbable that the climatic conditions have anything to do with this. Galveston is an exceptionally healthful place, and the general mortality rate is low (15.7). The high general mortality rate in Atlanta and in New Orleans is doubtless due to the large colored population. Notwithstanding a considerable colored population, the mortality rate of Galveston is low, and it will be observed that there is no relation between the general mortality rate and that from Bright's disease in any of these cities.

It has been suggested by some that the use of hard artesian-well water might have some causal relation, but this seems improbable, as other cities have a public water supply from the same source, and no such result is observed. To the writer there are two causes which seem more plausible than any of the explanations usually given: (1) The excessive use of meats in a climate in which proteids cannot be so readily metabolized as in a colder climate: and (2) the failure to recognize and properly manage acute infections. Scarlet fever is very often so mild that it is unrecognized and never treated. All the diseases of childhood are unusually light in Galveston. This is probably due to the higher resistive powers which result from the outdoor life at all seasons in a mild climate and on the seashore. Doubtless dengue and influenza, like scarlet fever and diphtheria, can leave a dormant lesion of the kidneys which gradually develops into a chronic nephritis, even though the acute symptoms from the original disease may not have been severe. This would appear to be a very important matter, and too much care cannot be exercised in attending to the after-effects of light attacks of acute infections.

INFANT FEEDING AND MILK MODIFICATION.[1]

BY RANSFORD E. VAN GIESON, M.D.,
OF BROOKLYN, NEW YORK.

In opening this discussion, my special object will be not the construction of formulas, but the study of principles upon which formulas should be founded. I desire to direct your attention to the composition of human and cow's milk, to the remarkable differences that exist between their proteid contents and how best to adapt the foreign element of cow casein to the digestive power of the infant stomach. Also to justify the use of cereal decoctions and high dilutions, as well as the use of cane sugar instead of cow lactose.

I select two definitions of the fluid called *milk* as best suited to our present purpose—one from the standpoint of the trained and expert chemist and another from a practical clinician, who is also a respected authority on milk analysis.

Dr. Bartley, in the fifth edition of his "Medical Chemistry," 1903, defines milk as an "opaque white fluid containing fat globules in suspension, albumin, sugar and salts in solution, and caseinogen in partial solution." Dr. Arthur V. Meigs, in the *Archives of Pediatrics*, October, 1902, says: "Milk consists of water, salts, fat, sugar and *something else*. That something else we have chosen to call casein, but what it really is, none of us need pretend to understand. Milk analysis helps us to know how to prepare food for babies, but the chemistry of casein is still in its infancy."

The composition of human milk in the living gland of the mother is never constant. There are subtle combinations effected therein which will always elude and baffle the most elaborate chemical research. Hence we find marked variations in the analyses given by different authorities, but by making a general average for each period of lactation we obtain results accurate enough to form a working basis for the modification of cow's milk to the purposes of infant feeding. In so doing we must not be misled into the belief that we should "imitate maternal milk." That is a simple impossibility, as none of the constituents of animal milk are chemically or physically identical with those of human milk, except the water and inorganic salts. Were it otherwise the cow could be led into the nursery, and the problem would be

[1] Read before the Medical Association of the Greater City of New York, June 13, 1904.

solved, and this discussion would be an entirely superfluous symposium.

Hoffman, in 1894, concludes that after the third week of lactation human milk varies but little. He gives the following average: Proteids, 1.03 per cent.; fat, 4.07 per cent.; sugar, 7.03 per cent.; ash, 0.21 per cent.

Judson and Gittings say: "The results of all analyses show that the proteid per cent. is very high in the first weeks after birth, diminishing after the thirtieth day. From the sixtieth day there is a decided and rapid fall. After the seventieth day the composition of the milk remains quite uniform. The fat is a varying constituent, ranging from 2½ to 4⅕ per cent. It differs materially from cow fat, being much more easily digested."

There does not seem to be any constant or fixed relation between the proteids and fat. There is always an excess beyond the apparent needs of the child. The sugar content ranges from five per cent. in the first month to seven per cent. during the remainder of lactation. The specific gravity of human milk will range from 1.029 to 1.032. It affords no certain guide to the quality of the milk, unless either the total solids or fat is known. In modifying cow's milk, the familiar rule to decrease the proteids and raise the sugar to the average proportions of the same in human milk is not always to be strictly observed. While we depend much upon comparative analysis of the two fluids, we must ever bear in mind that their most essential ingredients are not identical, nor must we ignore the vast clinical experience in this direction which established infant feeding on a safe and successful basis, long before milk analysis had reached its present accuracy. The essential knowledge which will guide us through the maze of conflicting theories and formulas is a thorough and familiar understanding of the great difference between human and cow casein.

The chief characteristic of cow casein is its ready coagulation into large indigestible masses, rich in fat. While human casein coagulates into fine, soft flocculi containing much less fat, easily acted upon by the gastric juice. If we examine the contents of a nursing infant's stomach one-half hour after a moderate meal, we find the chyme almost completely fluid and susceptible of filtration. The stomach contents of a child after a meal of cow's milk, at the end of three-quarters of an hour show casein clots still undigested. It is prudent and safe to look upon cow casein as admirably adapted to the purpose for which it was intended—the nourishment and development of the calf; but for the human species we may, with profit to the little ones intrusted to our care, regard it as a *foreign body*, capable also of sustaining infant life, after it is *adapted* to a stomach of feeble power, by nature designed for an easily digested food. Again, woman's milk, after coagulation, is thin, almost liquid. It does not require active peristaltic action to revolve its particles so as to become normally digested. It passes readily down from the nearly straight stomach into the intestines to be farther acted upon by their juices. With cow's milk the peristaltic action, normally weak, fails to soften the tougher clot, which very slowly finds its way from the stomach to the intestines, where portions still undigested are likely to prove sources of irritation.

The practical clinical fact here obvious is the important one that the digestive organs of young animals are adapted by nature to their normal food, and, as we cannot alter the organs, we must, in changing from the calf to the infant, modify the food to the organs. To do this we must so envelop, surround and come between the particles of cow casein not only by dilution, but also by the use of some viscid material, so that they shall not cohere in tough and indigestible masses.

We need also to expose a large surface of this foreign casein in a finely divided form and in *smaller quantities* than the *average amount* of *human casein* to the digestive action and feeble peristaltic motion of the infant stomach.

Dilutions of cow's milk have been made upon the assumption that because woman's milk contained 1½ per cent. casein, therefore we should make the mixture contain the same amount of cow casein. This error arises from following too closely laboratory inferences. Somewhat slowly this error has been corrected, and we now observe that the best authorities begin with high dilutions. For the first month with only one-half of one per cent. of proteids and 2½ per cent. of fat, and gradually reach one per cent proteids at the end of the month.

During the first month of normal lactation, the amount of human proteids may rise as high as 2⅗ per cent.; and some writers, disregarding and rejecting all clinical experience, have recommended undiluted milk for young infants because the caloric value of woman's milk is almost identical with that of cow's milk. Schlessinger, of Breslau (*Berliner klinische Wochenschrift*, No. 7, 1901), assumes the responsibility for this teaching, and advises small quantities of whole milk during the first month. Where the proteids are diluted to one-half per cent. with two per cent. of fat, we get excellent results for the first two weeks, all theory to the contrary.

Dilutions of milk make it necessary to add some form of sugar to bring the total amount in the mixture to 5 or 6½ per cent. Here, as in almost everything else connected with infant feeding, there has been considerable dispute. Personally I have always used pure granulated white cane sugar. I am not prepared as yet to believe that cow lactose and human lactose are identical in composition or effect. It is contended vaguely and without sufficient proof that it is more liable to set up fermentative changes. It is also frankly admitted that it is often better borne than cow lactose. After using it for

many years I have found no reason to change my views as to its superiority over cow lactose. Pure levulose, being a very easily assimilated fruit sugar, promises to give satisfactory results. Its expense at the present time would prevent its general use.

In considering the farther modification of cow casein beyond that of simple dilution, we find that for many years some form of cereal decoction has been empirically and successfully used in small quantities. As no starch is found in the milk of women or the lower animals, it has been objected to as unfit for milk modification, but clinical experience and more recent investigations prove incontestably that when used in proper quantities it is one of the most valuable means we possess for milk dilutions. Dr. Shaw (*Albany Medical Annals*, 1904) details a series of interesting experiments in connection with this point which are instructive and convincing, proving that starch in one-half per cent. solution is converted into erythrodextrin and maltose in the stomachs of young infants. He arrives at the following conclusions: "That the saliva of young infants contains a diastatic enzyme capable of converting small amounts of starch into maltose; that the diastatic action of the saliva may continue in the stomach as long as two hours after feeding; that on physiological grounds there is no reason why young infants cannot digest small quantities of starch."

The experiments were made on thirty-five infants, the youngest being six days old. Control tests of the starch solution were always made.

It has been taught that the attenuation of cow casein depends upon the degree of dilution, irrespective of the presence of starch. To determine this point, at the suggestion of Dr. T. M. Rotch, of Boston, the question was studied by Dr. F. W. White (*Boston Journal Medical Sciences*, December, 1900). The experiments justify the following conclusions: (1) "Dilution of milk with cereal decoctions of proper strength render the casein curd much more fine, soft and digestible than dilution with water; (2) "The above property is due mainly, if not wholly, to the starch in solution. The most desirable amount of starch in the milk mixture for practical use is approximately three-fourths per cent.; (3) "Diastase, by converting the starch to dextrine and maltose, promptly lessens and removes the action of cereal waters upon casein. Its addition, therefore, is not a practical measure when the action upon the curd is desired; (4)"Albumin water has no practical value as a diluent of milk; (5) "Lime water added to milk has no more effect than water upon the character of the curd produced in the animal stomach."

It was also found that this mixture, after pasteurization at 167° F. for thirty minutes did not interfere with the action of the starch, but rather improved it, the curd being somewhat finer after being heated.

The fat of cow's milk gives comparatively little difficulty. It should always be taken from fresh gravity cream. Centrifugal cream is still *sub judice*, and until we know more about it, it will be safe to take advantage of the top milk mixtures. The tables of Chapin and Holt are valuable and sufficiently accurate for home modification. Laboratory or prescription milk recombines the milk elements in any desired proportion after they have been separated by centrifugation. From purely theoretical inferences it would seem to be correct in principle, but clinical experience, according to Dr. Starr, does not bear out the theory. The natural fat emulsion is destroyed by the use of the separator, and in some way the digestibility of the proteids is diminished.

Milk may be farther modified by peptonization, whereby the curd is softened and partially converted into albuminose by pancreatin and bicarbonate of soda. This method is especially useful where digestion is weak and sufficient proteids cannot be assimilated. Where the digestion is normal it is not necessary.

Modification by pasteurization and sterilization may be considered as necessary evils, to be used when indicated and discontinued when the necessity is past. Of the two evils, pasteurization at 155° F. for thirty minutes is decidedly the lesser. Dr. Freeman (*Archives of Pediatrics*, Vol. XIV) reports that one million bottles thus prepared were distributed among the poor of New York. During the three years of its use the number of deaths from diarrheal diseases were less by 860 than in the three preceding years.

What we have already said applies to pure cow's milk and cream as the basis for modification, but for many years condensed milk has been very popular among all classes as an infant food. As an exclusive food it cannot be recommended, as it is usually used, especially among the poor, by simple dilution with boiled water. Children seem to thrive upon it, for a time at least, in spite of the very low fat percentage, but sooner or later the signs of malnutrition become apparent in the form of rachitis, scurvy or anemia. When properly diluted and fortified with cream, barley and lime water, five per cent., it can be continued for a long time without injurious effects. But where cream can be obtained good milk can also be obtained, and there is no reason in such a case for using it.

In conclusion, we cannot fail to observe that it is possible to feed infants by a variety of methods, founded on different theories, and have them gain in weight and vigor. It must be obvious that in all these methods some central fact or facts predominate and harmonize the difference in methods. It would seem, in reviewing those that are most successful, that the two chief factors are purity of the milk and the proper adaptation of the cow proteids to the capacity and power of the infant's digestive organs.

In this brief summary of our subject, my endeavor has been to make these facts the predominating feature. How best to modify and adapt the foreign elements of cow's milk for infants was long ago discovered by our fathers in pediatrics. Modern research has proven that they were correct in principle and practice. The findings of the observant clinician at the bedside usually precede those of the chemist in the laboratory. Mere chemical analysis is not always to be regarded as a true criterion of the value of food. The digestibility of the food represents its true value, and in infant feeding is the all-important question.

CICATRIZATION—BLOOD VESSELS IN ULCERS OF THE BLADDER.[1]

BY GUSTAV KOLISCHER, M.D.,
OF CHICAGO, ILL.

SINCE I have called attention to the fact that ulcers of the bladder are of a rather frequent occurrence in cases of chronic cystitis, and run a well-defined and typical course, this condition was rather uniformly recognized by the urologists and the treatment suggested and successfully employed by me was taken up by all genito-urinary men familiar with cystoscopy and endovesical work. I again wish to mention that this treatment consists in curetting the ulcers and cauterizing their bottom by means of silver nitrate in substance, or by employing the galvano-cautery. All this is done through an operative cystoscope.

This energetic and radical proceeding becomes necessary because these ulcers are the product of foci of dense infiltration, and because the bottom of these ulcers is covered with a thick coating which adheres quite strongly to it, so that even a concentrated solution of some caustic will never be able to reach the granulations in order to prove the desired reaction, if the coating was not previously removed. It is true that the above-mentioned treatment will always be a complete success so far as the disappearance of the ulcers is concerned. But in some cases, although the ulcer has disappeared, certain annoying symptoms will remain. This is especially true in cases in which the ulcers are not the consequence of a chronic cystitis, but are due to lesions of the mucosa inflicted upon an otherwise healthy lining of the viscus. These losses of substance are infected either at the time when the lesion was inflicted or the infection occurs later on. In this way, the epithelialization of the defects is prevented, and one or several ulcers are established.

These ulcerations have a decidedly different appearance from ulcerations due to chronic cystitis. The latter appear always on the summit of a little elevation, and show extensive surrounding infiltration because they are the result of a suppurative softening of a focus of inflammatory infiltration. The former are sunken in the mucosa, so that their bottom lies underneath the level of the bladder mucosa. Extensive surrounding infiltration is only exceptional, and very rare. We also, as a rule, miss the thick and miscolored coating which covers the bottom of cystitic ulcers so that in this variety the irregular granulations of the ulcer lie bare.

These ulcerations are of a traumatic origin, as a rule, due to instrumentation. The use of catheters with a raw surface, injudicious sounding or the producing of burns through a cystoscopic lamp, are the most frequent causes. In some cases, these traumatic ulcerations are the result of lesions inflicted by extraneous bodies introduced into the bladder by the patients themselves. In some cases the removal of the guilty foreign bodies and antiseptic flushings and instillations will suffice to bring about the clearing up of these traumatic ulcerations, and in the further decourse, accomplish the epithelialization of the defects. In stubborn cases, however, we have to again resort to curetting and cauterizing.

In four of my cases of this category I made the rather surprising observation that disagreeable symptoms, such as irritation in the bladder region, frequency of urination and occasional tenesmus persisted, although the urine was cleared up perfectly and repeated and careful systoscopic examinations proved with absolute certainly that the ulcers had healed up and complete epithelialization of the defects had taken place.

There is only one theory I have to offer for explaining this occurrence, and the results following the therapy employed seems to bear me out in my statements.

I noticed in most of my cases of traumatic ulcers that when the ulcer began to heal, quite large blood vessels loomed up in its neighborhood, and led to the circumference of the ulcer. It impressed me that these blood vessels might be something similar to the cicatrization loops which appear running to the ulcers in the cornea of the eye, and I actually do not know of any better comparison for this condition. These blood vessels appear in the number of two or three or four, and in approaching the circumference of the ulcer they show a meandering course; the loops lie very close to each other, giving the appearance of the diagram of a micrometer screw. It occurred to me that the persisting of these blood vessels might have something to do with the sensation of irritation of which the patients continued to complain, even after the ulcers had healed. I remembered the explanation that Hebra gave for the itching which carriers of varicose veins on the legs experience.

He claimed that the itching was due to the sensation produced by the very slow and torpid flow of the blood, in dilated and meandering blood vessels.

We observe similar sensation of itching, heaviness and frequency of urinary cells in cases of so-called bladder hemorrhoids.

[1] Read before the February, 1904 meeting, of the Chicago Urological Society.

I obliterated these blood vessels with the pointed galvanocautery of my operative cystoscope, and after the eschar was thrown off, which, as a rule, takes about a week, the symptoms had entirely disappeared and the patients remained well.

TUBERCULOSIS IN OUR PUBLIC INSTITUTIONS.

BY JAMES GREENWOOD, M.D.,
OF SAN ANTONIO, TEXAS;
SECOND ASSISTANT SUPERINTENDENT, SOUTHWESTERN INSANE ASYLUM.

TUBERCULOSIS is by far the most serious disease we have in an asylum, because its course is usually so rapid, there are always so many patients with lowered vitality in danger of becoming infected, and especially, since so little can be done to prevent expectoration of sputum laden with tubercle bacilli on clothes, bed, floor, walls, and everything around.

In all situations where people are confined, either by occupation, religious orders, poverty, or the requirements of law, as in asylums or prisons, tuberculosis is a serious problem with which to deal. Under these conditions we have lowered vitality from lack of fresh air, poor food, exposure and disease on one hand, and on the other, intimate contact of those already affected with tuberculosis, with the serious difficulty of taking proper precautions in the destruction of their infected sputum.

In an insane asylum a large percentage of our cases are demented, having little physical or nervous constitution, and are in constant danger of any infection, such as tuberculosis, pneumonia, or gastro-intestinal intoxication.

The acute cases are likewise in a state of lowered vitality, and present conditions favorable to infection with tubercle bacilli. These patients are in close contact with those already infected whose expectorating on everything around them is almost impossible to prevent. This sputum, laden with tubercle bacilli, dries, becomes dust, blows about here and there, the wards become infected and everything producing dust, as sweeping or dusting stirs them up for all to breathe,—so that patients, attendants and doctors are in constant danger of contracting the disease.

The tuberculosis record at the Southwestern Insane Asylum is as follows: During the twelve years of its existence there have been 392 deaths, of which 85, or 21⅔ per cent., were due to tuberculosis. Nine-tenths of our patients are between twenty and fifty-five years of age. Eleven-twelfths of our deaths from tuberculosis were at this age. The total death-rate per 1,000 living in the United States for this age is about ten, of which 4.4 to 4.8 is due to tuberculosis. In the asylum for twelve years we have had an average yearly death rate per thousand, treated for this age, due to tuberculosis alone, of 13. This is more than from all other diseases on the outside, and three times as many as are caused from tuberculosis alone in the United States for this age.

During the first three years there were no deaths from tuberculosis, but as the wards became infected, the death rate from tuberculosis has increased, until it has averaged 18 per 1,000 treated, for the last five years.

Table No. 1 gives the number of deaths each

Table 1.

Year to Sept. 1.	Total Deaths	Deaths due to Tuberculosis.	Average Daily No. of Patients.	No. Treated for Year.	Per Cent. due to Tbc.	Per 1000 Treated.

to tuberculosis. This is 19 per 1,000 treated. Of these nine, three died on Ward C, and three more were sent from this ward to the hospital after the disease was contracted. Six of these nine cases therefore contracted the disease on this

ward. This is the ward where our most demented cases are kept, and presents the most favorable conditions for contracting tuberculosis on account of the physical condition of the patients, and the difficulties of preventing those already affected, from infecting the ward.

Of these nine cases, eight were dementia, two being epileptic dementia; and this shows the influnce of the lowered vitality in predisposing to contracting the disease.

On the male side we have had during the last twelve months, 28 deaths, of which eight were due to tuberculosis. Four contracted the disease on Ward No. 7, a ward very similar to C, in the character of its patients, and the other four on Ward 4, where about nine-tenths of the cases are dementia. Of these cases eight were dementia.

At present we have six known cases of tuberculosis, all females, and all are at the hospital. Of these six cases, four contracted the disease on Ward C, the same infected ward that has been responsible for so many cases. We have a few suspicious cases besides, where examination of sputum and physical signs are negative, yet a slight cough, some loss of weight, an evening rise of temperature, make us suspect them of having the disease.

Our methods of prevention are as follows: All cases are sent to the hospital as soon as diagnosis. Some few patients are too noisy and violent, and have to be kept on the wards; these are sent to Ward C. At the hospital, when possible, patients are made to use spittoons, in which five per cent. chloride of lime is kept. Clothing on which they have expectorated is removed at once. All clothing, sheets, etc., of these patients is put in separate bundles, sent to the laundry with directions to be boiled before opened. All these patients use separate cups and glasses. Mattresses are disinfected by exposure to two per cent. formaldehyde gas for eight hours in a sealed room. The floor is washed with chloride of lime solution, instead of sweeping.

We have had no known cases of tuberculosis to develop at the hospital during the last year; so, considering the number of tuberculous cases present, and the difficulties in attending them, our methods have been very successful.

In Ward C we have made some radical changes. Any room in which a tuberculous patient has been sleeping is disinfected. The clothes are sent to the laundry to be boiled; the mattress disinfected by exposure to formaldehyde in a sealed room, the room, floor, walls and bedstead are washed with five per cent. carbolic solution. All the mattresses and blankets, pictures, etc., in this ward have been exposed for six hours to formaldehyde gas. The walls and floors are washed with five per cent. carbolic solution. There are no rugs, carpets or curtains to collect dust. The ward is swept with wet sawdust sprinkled over the floor beforehand. Often the floor is scrubbed with chloride of lime or five per cent. carbolic instead of sweeping. All mucopurulent expectoration is watched for, examined for bacilli and the patient examined so as to be isolated at the earliest possible moment. During the day this ward is kept almost free from patients. They are usually at the park, but when they come back, they go out on a long gallery.

What we most need is a special hospital for tuberculous cases, so built that they are given plenty of fresh air, yet easily disinfected. Another important preventive measure would be the enactment of a law requiring all cases admitted to be free from tuberculosis, as it is for other contagious diseases—smallpox, for example.

At present we have a law that no patient laboring under an infectious or contagious disease shall be admitted to an asylum. Tuberculosis should be included in this classification, and no known case should be admitted until a separate hospital is provided, where they can receive proper attention, and yet not endanger the lives of others.

COLLOIDS AND IONS.

BY WILLIAM R. WILLIAMS, M.D.,
OF NEW YORK.

THIS paper aims to present a few of those results of some of the more recent work of physiologists which bring us a little nearer to the secrets of vital processes. While this line of investigation has not as yet had much effect upon our immediate work as physicians, there is reason to believe that in time it will greatly advance our knowledge of physiology and pathology, and that therapeutics also will therefore gain by it.

Perhaps it may be well to begin with a review of some of the better known points. Much of the work has to do with electrolytes and ions. An electrolyte is a substance which, when melted or in solution conducts electricity. The actual passage of the current through such a solution is associated with certain changes called electrolysis. The molecule is found to be dissociated into two or more electrically charged particles called ions. Some of these ions are charged positively, and tend to migrate to the negative pole, the cathode; they are called cathions. Others have a negative charge and go to the anode; they are anions. For example, sodium chloride is an electrolyte, it is dissociated into two ions. Na is the cathion and goes to the cathode, Cl is the anion and goes to the anode. Sulphuric acid splits into three anions, two cathions, H and H, each with a positive charge, and one anion, SO_4, which has a double negative charge. In solutions of electrolytes a greater or less number of ions exist in a free state, even when not in an electric circuit, and move in all directions in that liquid.

When, however, an electric current is passed through the liquid, the ions assume a definite position relative to the current and tend to accumulate at one or other electrode. When the

ions reach the oppositely charged electrode, they part with their charges and become inert. Faraday said that the passage of electricity though solutions of electrolytes is possible only through the migration of these charged particles. Primarily, however, the dissociation is not affected by the current, but by the act of solution. H_2SO_4 is an electrolyte, but an attempt to pass a current through pure 100 per cent. sulphuric acid is unsuccessful. It is a non-conductor, it is not dissociated into ions. If a little water is added some of the molecules are dissociated into ions, and the liquid now conducts the current.

The ability of a solvent to dissociate the molecules is called its dissociating power. This varies greatly with different solvents. Water or possibly hydrogen peroxide has the greatest dissociating power, but the alcohols and other liquids possess it to a less degree. With the same solvent the degree of dissociation varies with the temperature, the strength of solution and the particular solid. In very dilute solutions all of the molecules are dissociated. The table shows the degree of dissociation of sodium chloride in water at 18° C. The strength of solution is expressed in gram-molecules per liter. A gram-molecule in a mass of a substance that weighs one gram multiplied by the molecular weight of the substance. This is called a mol, often abbreviated to m. A mol of sodium chloride is 58.5 g.

Dissociation of NaCl in H_2O at 18° C.

M per Liter.	Grams per Liter.	Per Cent. solution.	Degree of Dissociation.
M	58.5	5.85	0.68
$M/_2$	29.2	2.92	0.73
$M/_{10}$	5.85	0.58	0.84
$M/_{100}$	0.58	0.06	0.93
$M/_{1000}$	0.06	0.006	0.98
$M/_{5000}$	0.012	0.0012	0.99
$M/_{10000}$	0.006	0.0006	1.00

From this table it will be seen that the ordinary solutions of this salt are dissociated to a very great degree. The neutral salts of the strong mineral acids have about the same degree of dissociation.

Colloids.—The next subject that I would lay before you is that of colloids.[1] Mixtures of colloids and liquids appear in different physical states. (1) There is the solution, a more or less viscid liquid, called a sol, and when the liquid element is water a hydro-sol. (2) A soft solid, but made up of the solid colloid and of liquid components. This is a gel, and when the liquid component is water a hydrogel. A mixture of gelatin and water of the proper strength, (*e.g.*, ten per cent of gelatin) is liquid, a hydrosol, when hot; if it is cooled to about room temperature, it sets and becomes a hydrogel. If again heated it becomes liquid. By alternately heating and cooling, it may be changed from one state to the other indefinitely. Such a system is called "reversible." All colloids do not act in this way. Thus, if a hydrosol of silica becomes solidified, it cannot again be liquefied. It forms an "insoluble" or "irreversible" gel. It is often possible to change a soluble gel so that it is no longer soluble; thus, formaldehyde acts on a gel of gelatin so that heat no longer liquefies it. (3) There is finally the colloid alone without any admixture of liquid. It is a solid.

The change from the liquid to the solid state, and *vice versa*, depends upon various factors, the temperature, the strength of solution, the presence of other substances, such as mercury bichloride, chromic acid or its salts, osmic acid, formaldehyde or alcohol, or the electric current. Many of the experiments with colloids are very interesting. If white of egg is mixed with nine volumes of pure water, filtered, boiled, and dialyzed against water to remove most of the salts, a blue opalescent solution is formed, which is not coagulated by boiling. The solid constituent is an alkali-albumin-like body. It is present in the water as minute, discrete particles in suspension, and to their effect on light the opalescence and blue color are due. If now, by prolonged dialysis against pure water, more alkali is gotten out, the mixture becomes a gel, and when all of the alkali has been removed, the solid constituent is precipitated in flakes. If a free acid is now allowed to diffuse in, the process is reversed, and a blue solution is again formed, but the solid is now an acid-albumen. The substance is extremely sensitive to the action of acids or alkalis. For instance, if a pin-point is dipped into a strong solution of sodium hydrate, shaken in the air and then washed in 5 cc. of pure water, an alkaline solution is formed that will completely dissolve a considerable amount of the coagulum. In the alkaline solution it is found that the solid constituent has an electric charge that is negative in relation to the solvent. In the acid solution the solid is electro-positive to the solvent. At the point of precipitation it is iso-electric with the solvent. As it approaches the iso-electric point, the solution is exquisitely sensitive to the electric current. A constant current of a millionth ampère passed through the slightly alkaline, opalescent liquid leads to the formation of coagulated flakes at the anode, while the opalescence grows less at the cathode. Again, as the iso-electric point is approached, mere mechanical agitation is enough to precipitate the colloid.

In his book on "Insectivorous Plants" Darwin[2] has recorded some observations that bear upon this work. They have to do with the contraction of the tentacles of the insect-eating leaves of the sun-dew, Drosera. The movements of the processes are very slow. To contract down upon an object needs an hour. This position is maintained for hours, and finally the straightening of the tentacles needs one or more hours. These sluggishly moving tentacles were watched under a microscope while living. When the cells were at rest the protoplasm was perfectly clear. As they contracted under the influence of some stimu-

lus, a change that Darwin called "aggregation" took place. It consisted in the appearance of dark, opaque masses in the protoplasm that slowly but constantly change their form. The process of aggregation could be traced down the tentacle, pausing a while at the cell partitions, until it reached the base of the tentacle and spread to the body of the leaf. It also appeared in other tentacles near those first affected. So long as the contraction lasted the opaque masses were present. As the tentacle relaxed, the masses disappeared and the protoplasm again became perfectly clear. They first disappeared at the bases, and the clarification proceeded toward the apex. In older cells that had been stimulated repeatedly the tips of the tentacles always contained a few masses. In order to show this phenomenon, the cell must be alive and uninjured. Surprisingly delicate stimuli could bring it on. Solutions of various chemicals, mechanical stroking of the leaf, contact with inert foreign bodies, etc., were alike effective. He calculated the amount of ammonium carbonate necessary to cause distinct masses to appear within an hour, and found it to be less that 0.0005 mg. The living protoplasm acted exactly like reversible colloid.

When fixed by death, with or without reagents, protoplasm is still colloidal, but no longer reversible or soluble.[3] When so fixed it has a more or less definite structure. It is important to compare other colloids with protoplasm in this respect also. Many colloids have been used in this research, such as serum albumin, globulin, paraglobulin, the egg-white, and gelatin, separately or taken together. They have been fixed by the various methods used in histological work. In every case the coagulated mass has been found to have a granular or reticular structure, the meshes of which contain the liquid constituent of the sol. The resulting figure of the framework seems to depend upon the concentration of the solution, the fixative, the particular colloid or colloids used, the temperature during and after fixation, and the amount and kind of crystalloids or insoluble bodies present during the process.

If the egg-white solution mentioned previously is coagulated, and very thin sections, about one micron thick, are examined with an oil immersion lens, a fine net is seen and at the intersections are minute spheres, which are connected by fine trabeculæ. The diameter of the mesh varies from less than one micron to several microns, depending upon the factors mentioned above. If electrolytes are present, the mesh is larger, and the coagulation is more easily effected. Although the coagulated mass may have the same volume as the preceding solution, it is now made up of both solid and liquid constituents. This can be shown by purely mechanical methods in the egg-white gel, in gelatin, etc. Perhaps the most familiar example is a blood clot where the insoluble colloid fibrin contracts spontaneously under the ordinary conditions found in a blood clot.

If in the solution of the colloid there are also solid inert particles in suspension, the structure after coagulation is somewhat modified. Very finely divided particles of carmine were mixed with the egg-white solution. In the clot all of the carmine grains were found in the nodal points of the mesh, and the size of the mesh and thickness of the bars were increased near the granules. This closely resembles the structure found in certain secretory cells that contain insoluble secretory granules.

Perhaps the strongest evidence of preexisting structure in protoplasm is the aster figure of dividing cells, or the striations of muscle. It is a question whether these appearances are due to the disposition of different substances which are quite separate or whether a uniform colloidal solution would present similar figures if fixed while under a strain. To test this point films of solutions of the modified egg-white, of soaps and other colloids were stretched across rings of cork. Then a very small drop of mercury was run upon the film. This subjected the film to a definite strain, the lines of force radiating from the mercury. While in this condition the films were fixed. The solid part of the clot had a fibrillar structure, the lines radiating from the center. This would mean that in a collodial solution either a strain produces heterogeneity or structure which is fixed in coagulation, or else that the strain disposes the molecular aggregates of the colloid along the lines of force, although the exact pattern may not be identical before and after fixation. In any case, it does not point to the existence of two kinds of substance such as spongioplasm and hyaloplasm. Furthermore, the colloid thus fixed is doubly refracting, just as striated muscle is.

It is pertinent here to recall that a living worm has been observed in a living muscle fiber. As it crawled along it displaced the bands and rods, but it left no wake, as they immediately fell into position again and the fiber looked exactly as it did before. This is hard to explain if the muscle protoplasm has the kind of structure usually ascribed to it. Hardy, who has done much work on this subject, draws the following conclusions: Structure is produced by sub-mortem or post-mortem changes in the cell, that are associated with coagulation. Coagulation and fixation are alike in being a desolution with formation of irreversible molecular aggregates with liquid in the meshes. The structure may be modified by foreign bodies in the colloid. Secretion masses and the carmine grains are such foreign bodies, but some secretion masses may undergo changes after the death of the cell and so still further change the structure of the colloid. The alveolar cells of the orbital glands of kittens and puppies were fixed in absolute alcohol, and very thin sections were cut and mounted. These preparations showed the secretion granules distinctly, and at the edge of the section, where it was about two microns thick, places were found from which the granules had dropped out. At these points the cell had a honeycomb structure enclosing the

spaces that had been occupied by the granules. There was no evidence of inner structure in the protoplasm itself, and the trabeculæ seemed homogeneous and structureless.

Again, similar cells were mounted in the field of a microscope in such a way that they could be watched while being treated with various liquids. Cells fixed in alcohol were treated with more diluted alcohols. In 60 to 40 per cent. alcohol the cell and the individual granules had swollen to several times their former diameters. The granules had lost their staining properties. Stronger alcohol again contracted the cell and granules to their original size, but the granules did not regain their staining properties, and the final picture gave no clue as to the amount of distortion and change in the processes of fixation and dehydration. It would seem, therefore, that the typical net of secretory cells in these preparations is the optical section of honeycombed protoplasm distended by the secretory granules; that it is not a net within the protoplasm, but a net composed of the whole of the protoplasm.

Fixing the cells in osmic acid fixes the granules perfectly, so that they no longer swell or change in water. Then the net is the conventional net of fixed colloids, with granules at the nodal points, and the meshes of the sponge are simply liquid-holding spaces. Cells from many different tissues and animals were examined in this manner, and in all it was found that the cell protoplasm reacted to osmic acid or bichloride of mercury, just as a soluble colloid does to a reagent that converts into an insoluble colloid. This would indicate that there is no evidence that the structure discoverable in the cell body of these cells after fixation has any counterpart in the living cell, much of it is artefact and very different pictures of the same gland cells are gotten by different reagents.

Living *Paramœcia* and other protozoa[4] illustrate colloidal properties in very interesting ways. They grow more readily in slightly alkaline media. In these cultures the animals had a negative electric charge in relation to the water, they showed negative chemotaxis to weak hydrochloric acid, and when in an electric current they moved toward the anode. Those grown in an acid media had quite opposite affinities. If acid were slowly added to the alkaline culture until the reaction became weakly acid, the organisms in the electric current would slow their progress to the anode, then stop, and finally most of them would move toward the cathode. The electric charge of the colloid in these tests depended upon its environment, its charge being opposite to that of the culture media, as was the cause of the egg-white solution.

Nucleo-proteids[5] have acid characteristics, the degree of acidity depending on the amount of nucleic acid present. This acid is most abundant in the chromatin of dividing cells and the heads of spermatozoa, hence their affinity for basic dyes. The extranuclear proteids are chiefly basic and are stained by acid dyes. There is some evidence to show a corresponding electrical difference between these classes of matter. The chromatin is electro-negative, the cytoplasm electro-positive. The difference of potential is greatest at the time of cell division, and possibly it modifies the figures, which suggest the lines of force in an electric field. If the different parts of cells have these electrical charges, then free cells which are relatively rich in nuclear substance, and to a greater extent free nuclei, should migrate against the electrical current toward the anode; cells that are chiefly cytoplasm should be less negative or even positive.

To test this, isolated cells from various tissues and as fresh as possible were put into $^{n}/_{4}$ cane sugar solution—which is isotonic with physiological salt solution—mounted on a slide and watched while a current of electricity was passed through. The rate of motion was measured by a micrometer. Frog's blood much diluted with the cane sugar solution was examined in this way. Most of the red cells moved slowly, 120 microns a minute, toward the anode, some were stationary, and a few were positive and moved with the current. The small leucocytes were distinctly negative, and went up the field at the rate of 1,500 microns a minute. The medium-sized leucocytes were slightly negative, but a few were neutral or even positive. The large leucocytes were decidedly positive, going down the field 120 microns a minute.

The same results were obtained from minced spleen or thymus. If the current was reversed, all cells stopped and started off in the opposite direction. Sperm heads from the winter frog were strongly negative and raced for the anode at 2,000 microns a minute. The testes of these frogs contain large cells, Sertoli cells, consisting of a round mass of protoplasm with a bunch of spermatoza heads at one pole. Such a cell orientated itself in the current with the sperm heads toward the anode, and sometimes the whole cell would move slowly up the current. A reversal of the current was followed by the slow rotation of the cell until the orientation was again complete, when the cell would again be pulled to the anode with the small end in advance. If an object of this shape were moving freely in a liquid the blunt end would always be in front, and the small end would follow like a rudder. These tests seem to bear out the hypothesis of the electrical charges very well. The cells which had the greater relative amount of chromatic substance were most strongly negative. The Sertoli cell in particular showed the greater negativity of the smaller part, the sperm heads, rich in chromatic substance, and the positive charge of the large mass of the cell protoplasm.

The *effect of ions* on different kinds of protoplasm has been the subject of much study. I will refer to a few of the experiments and their results:

Medusa.[6]—The medusa or jellyfish, so often

seen propelling itself slowly along the surface of the sea, is made up of an umbrella-like gelatinous mass, from the edge of which dangles a fringe of tentacles. Within this bell, corresponding to the handle of the umbrella, are the mouth parts. In sea water the bell contracts rhythmically by virtue of muscle fibers that radiate like umbrella ribs. This contraction forces the animal through the water. If now a cut is made that severs the ring at the edge of the bell from the central portion, this ring will contain practically all of the central nervous system of the animal. If these two parts are put in sea water the ring contracts rhythmically, just as the entire medusa did when intact. The central part, however, lies motionless.

Attempts were made to find the effect of various electrolytes on the central portion. It was put in a $^{5}/_{8}$m. solution of pure sodium chloride in water. This solution is about isotonic with sea water. The bell at once began to beat, and the rate increased until it was hardly possible to count the contractions. Another solution was prepared containing about the same amount of sodium chloride and in addition about $^{1}/_{300}$ m. $CaCl_2$. In this, after a latent period of a few minutes, the bell began to beat, and the contractions were more like those of the normal medusa in sea water. In other solutions, with about $^{1}/_{28}$ m. $CaCl_2$ or more, the beating was wholly absent. Strontium or magnesium acted like calcium in stopping the beats. Barium, however, acted very differently, for the beats started at once, and were very forcible. They did not last so long, the barium seeming to be more poisonous than pure sodium chloride.

It was thought that perhaps the calcium in the sea water prevented the beating of the central part of the bell in that medium. To test this, NaF and Na_2HPO_4 were added to sea water. When a little more than enough to precipitate all of the calcium of the sea water had been added, the central part of the bell acted just as it did in pure sodium chloride solutions. It would seem, therefore, that the calcium in the bell prevents its beating, and that the reason that it beats in those various media is that the excess of calcium is gotten rid of. There seems to be a limit to this diminution of calcium, however, for after a while the beats stop in the sea water to which the NaF or Na_2HPO_4 was added. Then, if the bell be put back into sea water, or solutions containing calcium, the beats begin again, after a latent period of a few minutes. This latent period seems to be the time necessary for some of the Ca ions to diffuse into the bell, or else for the F or PO_4 to diffuse out, or perhaps for both of these changes.

The inference from these experiments is that if a certain equilibrium exists between the sodium and calcium ions, the isolated center of medusa will beat rhythmically. If, however, this equilibrium is disturbed in either way, the beats will be modified or stopped. In ordinary sea water these ions are not present in suitable proportion.

The marginal ring is much less susceptible to the influence of calcium. It will beat in pure sodium chloride solution about as it does in sea water, and about as the uninjured jellyfish does. If calcium be added, even in considerable amounts, the only effect is to slow the beats a little. It will be remembered that the margin contains the central nervous system, and this suggests that while the inhibitory effect of calcium on the muscle is marked, it is very slight in the nervous centers.

Various muscle from the vertebrates is just as sensitive to the action of ions. The most convenient animals to work with are, of course, the cold-blooded ones, because their isolated fragments can be kept alive so much longer.

In the ventricle of the turtle,[7] strips of muscle were cut both from the venous end and from near the apex. Those from the venous end contained ganglia. If these strips are put in the animal's own serum, or in the artificial serum called Ringer's solution, they beat rhythmically. Ringer's solution contains NaCl 0.7 per cent. ($^{m}/_{8}$), KCl 0.05 per cent. ($^{m}/_{150}$) and $CaCl_2$ 0.026 per cent. ($^{m}/_{450}$). The apical strips did not beat in these liquids, and they only were used in the following experiments.

A strip from near the apex of the ventricle was put in a solution of NaCl about isotonic with the animal's serum. There was a latent period of an average duration of one hour, in which the muscle was quiet. Then rhythmic contractions began. At first the beats were small and infrequent, but they steadily increased in extent and frequency to a maximum, then they gradually faded away and stopped altogether. The average duration of this rhythmic activity was two hours. During this stage the strip grew steadily longer, that is, there was a progressive loss of tone. At the end of this stage the muscle did not react to mechanical or electrical stimuli. These exhausted strips were then put into Ringer's solution. They began to beat again after a few minutes, and continued to do so for twenty-four hours, but somewhat irregularly.

Other exhausted strips were put into a solution containing only NaCl and $CaCl_2$. The $CaCl_2$ at first amounted to only 0.1 g. in a liter. Later it was increased to 0.2 g. In this solution the beats started promptly, were perfectly regular, and continued for several hours, but not for so long as in Ringer's solution. There was also a progressive increase of tone.

To recapitulate, the fresh apical strips, put into sodium chloride solution, began to beat rhythmically after a latent period, the beats continued for about two hours and then stopped, and there was a progressive loss of tone. These exhausted strips could be made to beat again for twenty-four hours somewhat irregularly in Ringer's solution, or for several hours and with perfect regularity in a certain solution of sodium and calcium chlorides, and in this latter solution the tone steadily increased.

If, on the other hand, the fresh strips were put into a solution containing sodium and potassium chlorides in the proportions found in Ringer's solution they did not beat. If the potassium was not too strong the muscle was not harmed, and it would beat for several hours if transferred to Ringer's solution. There was also loss of tone.

If the fresh strips were put into a solution of NaCl 0.7 per cent ($^{m}/_{8}$) and $CaCl_2$ 0.026 per cent ($^{m}/_{450}$) there were vigorous beats for four or five hours. The tone at first decreased, but later there was a steady increase of tone ending in a distinct calcium-rigor. After this rigor developed, there were no further beats in any of the solutions tried. Before the rigor developed, the strips could be made to beat for a long time by transferring them to Ringer's solution.

To determine if possible the effect of oxygen[8] on the muscle, the solutions were boiled and cooled under oil. In these oxygen-free solutions the beats started as before, but lasted for a very short time only. Then solutions containing hydrogen peroxide in addition to the various salts were used. In such solutions an abundant supply of oxygen was provided. The oxygen alone could not start the beats, but if the solution contained sodium chloride also, the beats began and continued without exhaustion for twenty-four hours.

Again, caffeine was tried because of its stimulating effect on muscle. It did not start the beats, but if it were added to the sodium chloride solution, the beats were stronger.

That calcium is not necessary is suggested by the fact that the strips were made to beat in solutions that contained salts whose anions precipitate calcium.

In a recapitulation of the results of these researches one must first note the latent period. This is attributed to shock or else to the time needed for the diffusion out of potassium or other ions. After this, in a suitable environment, the strips beat rhythmically. Sodium and chlorine ions are necessary for the production of rhythmical activity in the apical strips from the turtle's ventricles. Caffeine intensifies the beats but cannot start them. Oxygen cannot start the beats, but it delays the exhaustion noted in sodium chloride solutions, and will cause the renewal of beating after exhaustion in sodium chloride solutions. Oxygen and sodium chloride will keep the beating going as long as Ringer's solution. Solutions of the oxalates that precipitate calcium will let the beats begin if sodium and chlorine ions are present. Sodium salts tend to produce a loss of tone. Calcium tends to make the beats slower and regular, and to produce an increase of tone that will go on to the production of a permanent rigor. Potassium may slow the rhythm, antagonize calcium, especially if sodium is present in normal amounts, and prevents spontaneous contractions in Ringer's solution, or in the animal's own serum.

Voluntary striated muscle also was found to be profoundly affected by ions. The gastrocnemius of the frog has been used in practically all of the experiments. It showed changes in tone, rhythmical contractions and a new phenomenon called "contact irritability."

Changes in Tone.—The experiments on muscular tone[9] were chiefly concerned with solutions much stronger than those in the body fluids. Thus, in Ringer's solution the strength in KCl is about $^{m}/_{150}$ and of $CaCl_2$ $^{m}/_{450}$, while the effects mentioned below needed a strength of KCl of $^{m}/_{80}$ or more. The experiments are interesting, however, and worth noting. If the frog's gastrocnemius was put into a solution of $^{m}/_{8}$ KCl, there was, after a short latent period, a very marked tonic contraction that lasted from twenty to one hundred minutes, during which there was no fluctuation whatever in the curve. Other potassium salts had the same effect. Those tried were the chlorate, nitrate, sulphate, iodide, bromide, chromate, bichromate, ferrocyanide, oxalate, cyanide and tartrate.

Weaker solutions had a similar but less intense effect. The weakest that caused distinct tone was $^{m}/_{80}$, about 0.09 per cent. If the contracting muscle were removed from the KCl solution, and put into $CaCl_2$, the muscle relaxed; or if $CaCl_2$ were added to the KCl solution the contraction was prevented or stopped. By the alternate application of KCl and $CaCl_2$ the muscle beat rhythmically and as rapidly as 70 times per minute. It was found that immersing the nerve only in the liquid had no effect. I have not seen a report of any such experiments with skeletal muscle with solutions comparable in concentration to the blood serum but unstriped muscle[10] was found to react in exactly opposite ways to strong and to weak solutions of these salts.

Rhythmic Contractions.—In another group of experiments[11] the frog's gastrocnemius was put into $^{m}/_{8}$ NaCl solution. The muscles soon began to twitch rhythmically just as the heart muscle did, and it continued to do so for several days, or about as long as the muscle lived. When a very small amount of a soluble calcium salt was added, the twitchings no longer occurred, but the muscles lived much longer than in a pure sodium chloride solution. Its living condition was determined by its reaction to other stimuli. This would seem to mean that the reason the frog's skeletal muscles do not beat rhythmically like his heart is that the blood contains Ca ions. The exised muscle itself contains calcium, and if this theory holds, salts of sodium, whose anions precipitate calcium, should have a more powerful effect in causing twitching than the chloride. Therefore, solutions of sodium fluoride, oxalate, carbonate, phosphate, etc., of the proper osmotic strength were tried. The hypothesis found confirmation, for in these solutions the beats were stronger than in the chloride solution.

It has also been shown previously by another experimenter that the injection into the body of living animals of a salt that is apt to precipitate

calcium is followed at once by twitching of all the muscles. It may be possible, therefore, that the accumulation in the blood of such acids, *e.g.*, oxalic acid, might lead to muscular twitchings and irritability. If this should prove to be the case, the condition might be cured by the administration of calcium. Lithium, rubidium and cæsium act like sodium. Magnesium and strontium act like calcium. Barium acts very differently. When a little $BaCl_2$ was added to the sodium solution, the weak twitchings became stronger and more tetanic. In a solution containing only barium the beats occurred and had the same tetanic character. They did not, however, last for more than a few hours. This is doubtless due to the poisonous action of all barium salts. The beats do not take place in sodium chloride of a less concentration than $^m/_{16}$, but in $^m/_{64}$ $BaCl_2$ they always were seen and sometimes in $^m/_{128}$. Such cathions as Zn, Pb and Cd also caused beating, but they are very poisonous except in very dilute solutions, and in the dilute solutions the muscle rapidly imbibes water, which alone suffices to stop the activity. It is, therefore, not surprising that the beating did not last long in these solutions.

Sodium citrate had a very interesting effect. Citric acid does not precipitate calcium in the tissues, but it prevents its action in other ways, preventing the coagulating effect of calcium. It also caused the twitching in much weaker solutions ($^m/_{200}$) than did sodium chloride. These experiments have special interest when compared with the medusa experiments where the effect of calcium on the central part of the swimming-bell was very similar. There, too, sodium citrate had a like effect, for if it was added to sea water the isolated center began at once to beat.

Contact Irritability[12]—In the work with voluntary muscle a new phenomenon, called "contact irritability" was discovered. When the frog's gastrocnemius was left for from one to three minutes in various solutions of a sodium salt whose anion precipitates calcium, there was no effect. If the muscle was then taken out of the liquid and exposed to air, it at once went into a condition of tetanus, or made several strong, tetanic contractions. If it was again restored to the solution, it relaxed at once. This process could be repeated many times by alternately putting the muscle into the solution and into air. The salts that acted in this way were sodium fluoride, carbonate disodic-hydric-phosphate, sodium oxalate and also sodium citrate. If instead of being exposed to air the muscle was exposed to oil, cane sugar solution ($^n/_4$ to $^n/_8$), glycerin, CO_2 or mercury, the same contractions were noted. The reaction was not due to evaporation, for it occurred in an atmosphere saturated with water vapor; nor to lessening of the hydrostatic pressure, for it occurred in mercury and other liquids under greater pressure than in the original solution. Solutions of the corresponding salts of lithium, potassium, magnesium or ammonium had no such effect. The only salt not a sodium salt that had this effect was ammonium sulphate, and it is interesting to note in this connection that the SO_4 ion acts like calcium in counteracting the toxic effect of pure sodium chloride on cells of fish eggs. Some other experiments suggest that the irritability is due to action on the nerve end-plates rather than on the muscle fibers.

If the nerve alone is put in the solutions, the effect is very different. The muscle and nerve were mounted so that the nerve only was immersed in $^m/_{10}$ sodium citrate. No reaction was noticed during the first five mintues, but then the muscle began to contract rhythmically. The beats increased in force and the tone increased, until a condition of tetanus resulted. If the nerve were lifted out of the solution the muscle slowly relaxed. It again contracted if the nerve were restored to the solution, and so on almost indefinitely. After the relaxation of the muscle had taken place in air the nerve was in a state of extreme irritability, so that mere contact with any solid or liquid caused contraction of the muscle. The nerve was more sensitive to electrical stimuli also. These experiments show that ions have a marked effect on the irritability of nerve and muscle, but not enough has been learned about contact irritability to warrant further conclusions.

When these salts were injected subcutaneously into rabbits they had a like profound effect.[13] Ten cc. of $^m/_1$ sodium citrate solution caused general muscular twitchings, tetanic contractions of the limbs and sometimes general convulsions, reflexes were exaggerated and incoordination of the hind legs was noted. The twitchings began at once at the site of injection, and in ten or twenty minutes on the other side of the body. With repeated smaller doses of the solution, 5cc. daily for a month, a chronic state of hypersensitiveness was produced, and it lasted for a month after the administration of the salt had been stopped.

The action on the intestine of these same salts in purgative doses was studied in rabbits.[13] The rabbit was anesthetized with morphine and its intestines exposed. When the salts were given by mouth or subcutaneously, greatly increased peristalsis was seen after ten or fifteen minutes. The solution was also injected directly into the lumen of the intestine with a similar result. About 30 cg. of sodium citrate (10 cc. $^m/_8$ solution) was needed. One or two cubic centimeters injected into a vein was as effective, and it acted in one or two minutes. In other rabbits used as controls without morphine or laparotomy, the salts purged in about an hour. The stools were from two to six times the normal amount and were semi-liquid. In the rabbits whose intestines were examined there was always excessive secretion, so that within twenty or thirty minutes, the intestine contained much clear yellow liquid that was not bile. Loops of intestine isolated by ligature showed the same increased secretion. Calcium, too, showed its usual inhibition. The active peristalsis due to the purgative salt could be al-

most entirely suppressed by the injection of a like amount of $^{m}/_{8}$ $CaCl_2$. When the calcium chloride was injected into a vein, the effect in checking peristalsis was noticed within one or two minutes, and within ten to twenty minutes after injection subcutaneously or directly into the lumen of the intestine. Calcium chloride was more effective in stopping peristalsis than chalk.

If the purgative solution was painted upon the peritoneal surface of the intestine it caused a great increase of peristalsis almost immediately. This was promptly stopped by painting a solution of $CaCl_2$ upon the same part of the intestine. In one experiment this alternate stimulation and suppression of peristalsis was repeated sixteen times without any apparent decrease in the effect. Barium chloride, also, acted here as it did elsewhere. It was by far the most powerful, and its poisonous effect was often shown by the death of the rabbit. Barium chloride is used as a purge by veterinarians, the hypodermic injection of a gram being enough to purge a full-sized horse. In the rabbit if a drop of $^{m}/_{8}$ $BaCl_2$ solution was put on the intestine, the circular fibers contracted and formed a deep, ring-like depression, as if the intestine were ligatured. This ring of contraction then travelled down the gut. To counteract the barium chloride about forty times as strong a solution of calcium chloride was needed.

Other experiments with the frog's gastrocnemius show that the presence of oxygen has a marked influence on the muscle.[14] In an atmosphere of oxygen the irritability of muscle persisted for a much longer time than in air, usually lasting for forty-eight hours. If the muscle was kept in air rigor mortis came on within a day; in oxygen there was no evidence of it for three or four days, that is, until the muscle was destroyed by putrefaction. Fatigue is much delayed in oxygen, and if a fatigued muscle is allowed to rest in oxygen it recovers from the state of exhaustion.

Although the aim of this paper is primarily to call attention to experiments, it seems desirable to give a short synopsis of Mathews'[15] conclusions as to the nature of nervous impulses. He says that the transmission of an impulse is associated with the temporary gelation of successive particles of nerve protoplasm, that in fact this wave of gelation *is* the impulse. This gelation is due to electrical change. In motor nerves it is induced by negative electricity, whether in a direct current or in charges of anions. Irritability is increased by conditions that facilitate gelation. These are negative electricity from proximity to the negative pole of a current (which explains katelectrotonus) or from a preponderance of anions. Irritability is lessened or inhibited by conditions that tend to prevent gelation. These are a preponderance of cathions, or proximity to the positive pole. Ions act electrically rather than chemically. In general, all anions stimulate or increase irritability of motor nerves, all cathions depress or inhibit irritability. While the quality of the effect depends upon the sign of the charge, the different quantitative effects of the various ions depend upon the amount of the charge, which varies with the valence, and also upon the ease with which the ion parts with its charge, in which respect ions vary extremely. The algebraic sum of all these factors determines whether a given salt, or rather a group of ions, will depress or stimulate, and how great the resultant effect will be. This theory is very fascinating, and more work that bears upon it is eagerly awaited.

Much other work has been done along these lines, and one is tempted to go no and recount many experiments on various tissues, but for fear of presuming too much upon your patience I will mention only a few results with some embryonic forms.

Of course there must be some general laws governing the action of all these ions. If these laws can be discovered, the results may be far-reaching. A decided step in the right direction seems to have been made and the effect of ions can be foretold at least in their action on one form of protoplasm.

The eggs of a certain marine fish after fertilization[16] were washed in distilled water to remove the salts. They were then put into solution of known composition. It was found that every solution of a single salt had a poisonous effect, and that the eggs died after a time. The development was carefully watched to determine the least concentration that would kill in thirty-six hours, also in sixty-four hours. To learn the comparative effects of cathions it was necessary to eliminate the effect of the anion. This was accomplished by using the various cathions in combination with the same anion, and chlorides were used for this purpose. The cathions used were K, Na, Ba, Ca, Al, Zn, Fe, Co, H, Cu, etc. It was found that the toxic effect of the cathions varied inversely as their solution tensions. To test the anions it was necessary to eliminate the varying effects of different cathions. This was done by using salts of sodium, those used were the cyanide, hydrate, iodide, bromide, chloride, oxalate, acetate, sulphate, etc. Here, too, the effect was inversely as the solution tension.

Combining the two series of results the effect of any electrolyte is inversely as the sum of the solution tensions of its ions. This law makes it possible to get a formula for comparing the activity of salts that do not have a common ion, provided the solution tensions are known. For example, given that $^{n}/_{3000}$ HCl will kill in twenty-four hours, what strength of KI will accomplish this result? The calculated result was 0.189 n KI, the result found by experiment was 0.175 n KI, a difference that is within the limits of experimental error. Perhaps further work will be necessary to firmly establish this law, but it is very interesting as a mark of scientific advance, in that it is possible to have a formula for the effect of the various ions on at least this form of protoplasm.

Another series of experiments has brought out some very interesting facts in connection with the development of eggs.[17] The sea urchin is an animal in which the sexes are separate and in which parthenogenesis is unknown. In sea water unfertilized eggs may begin to segment, but the process never goes beyond the earliest stages represented by a group of a few cells. The fertilized egg in sea water almost immediately forms an egg membrane that enclosed the embryo. In the various other solutions tried, eggs that had not been fertilized did not develop this egg membrane except in solutions of calcium chloride and a few other salts, all of which tend to coagulate protoplasm. In these solutions, however, it was not found possible to have the development of the embryo go far enough to be significant.

To eliminate the possibility of chance fertilization as much care was used as in a surgical laparotomy. The dishes and instruments were sterilized, the females were carefully washed in distilled water for a considerable time (distilled water is quickly fatal to the spermatozoa), the eggs were removed by operation, and a very careful and complete series of controls was tried in every case to avoid all the different chances of error. The technic was so effective that no instance of chance fertilization was ever found. With these precautions efforts were made to find something that would cause parthenogenesis. Solutions which are not in themselves too poisonous, and which have a much higher osmotic pressure than sea water were found to answer the purpose. At first the eggs were left in such a solution indefinitely; they did not develop but died. Finally it was found that if the unfertilized eggs were put in a mixture of equal parts of sea water and 2½ n $MgCl_2$ for two hours, and then were put into ordinary sea water, they went through the morula, blastula and gastrula stages, and formed plutei which lived for several days. Plutei are freely swimming forms with an endoskeleton, and one metamorphosis subsequently completes the development.

In a laboratory it has not yet been found possible to have fertilized sea urchin's eggs develop beyond this point, probably because of microorganisms in the sea water. Although the plutei looked exactly like perfectly normal ones, there were some points in which the development differed from that of the fertilized eggs. The fertilized eggs form plutei in about twenty-four hours, the plutei swim about at the surface of the water, and practically every egg develops to this point. An egg membrane is always formed very early. The parthenogenetic eggs develop more slowly, in forty-eight hours or more; they do not develop an egg membrane, and this leads to the production of bizarre forms of irregular shape, due to the fact that the cells are not properly bound together; the plutei do not rise to the surface of the liquid, but swim around near the bottom of the dish; a much larger percentage of the eggs die. The striking fact, however, is, that many do develop into plutei that look exactly normal and live about as long and develop about as far as do the fertilized eggs. Solutions of non-electrolytes of equivalent osmotic pressure, such as cane sugar or urea, are as effective as the $MgCl_2$ when used in the same way. Therefore the effect is not the peculiar action of ions.

The eggs of a certain marine annelid, *Chætopterus*,[18] could be made to develop parthenogenetically, at least to a point where free swimming embryos were formed, in the same way and also by treatment for several minutes with sea water to 100 c.c. of which less than 0.4 g. of KCl had been added. Moreover, they developed when left permanently in 100 c.c. of sea water to which 0.007 g. of HCl had been added. It has long been known that a certain form of crustacean, *Branchippus*, can be grown in fresh or sea water, and that when it grows in sea water it assumes such different characters that it had been classified under another genus. Furthermore, in fresh water fertilization is necessary for the development of the eggs, while in sea water parthenogenesis occurs. All this seems to mean that the egg has within itself the power of development, but something from outside is necessary to start the process. Withdrawing water from the egg by osmosis may accomplish this, and also in some forms the presence of certain ions in certain concentrations, which act catalytically, such as KCl or HCl in the annelid mentioned. Perhaps the sea water acts on *Branchippus* eggs in both of these ways.

This paper has presented a somewhat disconnected mass of experiments, but they seem to me to be of great interest. Some facts which have long been known, such as the aggregation effects seen by Darwin in the sun-dew and in other plants also, and the profound change in the morphology and development of the *Branchippus*, assume a new importance. They are no longer isolated phenomena, but are seen to be but illustrations of quite general properties of protoplasm. The protoplasm itself, so long mysterious, is yielding its secrets to the study of colloids and physical chemistry. The study of the effect of ions upon protoplasm has advanced so far that general laws governing their action have already begun to be formulated. Practically all of the experiments have been verified by different observers working under different circumstances in different places, so they are pretty well established.

Work along other lines, such as the ferment action of colloidal solutions, the effect of ions on the kidneys, on nerves, etc., has given results as interesting, but this paper has already reached a sufficient length, so I will not mention them. Work in this field is full of promise; it is extending our knowledge into fields that a few years ago were called "unknowable," and it seems sure to exert a very great influence on the science of medicine.

MEDICAL PROGRESS.

MEDICINE.

Etiology of Toxic Erythemata.—It seems almost impossible to reach any positive grouping manifestations of erythematous skin diseases. JAY F. SCHAMBERG (*Jour. of Cut. Dis.*, October, 1904) makes a laudable effort to reach some tentative working basis for such a classification. (1) Bacterial and protozoal toxins. (2) Ptomains. (3) Leucomains and other metabolic poisons. (4) Drugs. It seems probable that in scarlet fever, measles, rubella, smallpox, typhus, influenza, pneumonia, malaria, gonorrhea, rheumatic fever, cholera, typhoid and so on, rashes are due to products enumerated under the first group. In certain instances, viz., where the exciting agent of the disease is found present in the affected cutaneous tissue, there is proof positive that there is relation between the two. This has not yet been proven definitely for the rashes occasionally seen in purpura and malaria. Under this group also are to be classed the rare urticarial eruptions sometimes seen in patients suffering from circumscribed abscesses, deeply situated. Group 2 comprises the basic organic alkaloids which are produced by the action of bacteria on nitrogenous matter. Vaughn classes them as follows: (*a*) Muscle poisoning; (*b*) fish poisoning; (*c*) meat poisoning; (*d*) milk poisoning; (*e*) cheese poisoning; (*f*) vegetable poisoning. The poison occurring in muscles is not a putrefactive product, for it cannot be found after decomposition has begun. Fish poisoning may result from eating certain species of fish which are always poisonous; from eating fish which are poisonous during spawning season; from eating fish which are affected with bacterial disease and lastly those which have undergone putrefactive change. Ergotism and pellagra are the best examples of vegetable food poisoning. The leucomains belong to two chief groups, the uric acid group and the kreatinin group. Brunton believed that the intellectual apathy seen after overeating is in part attributable to peptones. The author endeavors to show that nearly all of the diseases included in the erythema family, are produced by the presence in the circulating fluids of the body of a chemical poisoning. That these poisons have very widely dissimilar origins is unquestionably true, and yet so closely kin are they as to be almost indistinguishable by chemical analysis. From fifteen to thirty per cent. of patients injected with horse serum develop eruptions. The history of these cases is strikingly similar to that of the exanthemata. The author concludes that it is justifiable to reason by analogy that nearly all cases of erythema multiforme and nodosum, urticaria and purpura, are the results of the circulation of chemical poisons. Even on close examination of the urticarias of nervous origin, it seems probable that these are due to chemical rather than to vasomotor changes.

Early Diagnosis of Pulmonary Tuberculosis.—That the profession must go back to old and well-tried methods—clinical history and physical examination—in making the early diagnosis of this disease, is the opinion of W. F. CHENEY (*Am. Med.*, October 22, 1904). Of the newer methods, sputum examination does not inform early enough; tuberculin may give a reaction when no active tuberculosis is present, and may fail to give a reaction when active tuberculosis is really present; while the X-rays may confirm what physical examination has already discovered, it does not reveal anything that cannot be found out in other ways. Sources of error in diagnosis may be set down as three: (1) Preconceived ideas,—the physician's mind is made up beforehand that the patient has or has not tuberculosis. (2) Inattention to details. The changes that are dealt with in the early stages of tuberculosis are slight, and it is by many little things that by themselves mean nothing, but put together mean everything, that a diagnosis must be reached. (3) Lack of persistence in the examination is often at fault. One investigation is not sufficient, and the evidence must be gone over several times.

Sclerosis and Dilatation of the Coronary Arteries of the Right Heart by Digitalis.—A case is reported by T. V. OPENCHOWSKI (*Berl. klin. Woch.*, October 3, 1904) of rheumatic endocarditis and endarteritis with complicated valvular lesions. On two occasions when given digitalis, the symptoms of broken compensation were aggravated in each instance. The author made a diagnosis of dilatation and sclerosis of the right coronary artery and this was later confirmed by autopsy. Openchowski some years ago advanced the theory that digitalis manifests a tonic action on the left heart, by distending the left coronary artery and at the same time weakens the workings of the right ventricle, by contracting the right coronary artery. The case noted afforded an opportunity of demonstrating this for the first time on the human subject. The indiscriminate use of digitalis is therefore ill-advised and may lead to serious overtaxing of the right ventricle.

Does Increased Molecular Concentration of the Blood Warrant a Diagnosis of Bilateral Kidney Disease.—This subject is discussed by A. LOEB and C. ADRIAN (*Berl. klin. Woch.*, September 26, 1904), who report a case of carcinoma of the left kidney, with the right perfectly normal and a freezing point of the blood of 0.635° C. They believe that this concentration of the blood in spite of the efficiency of the right kidney, was caused by the suddenness with which the additional work was thrown upon it through the rapid growth of the tumor of the other kidney. They conclude that unilateral kidney disease (excluding other causes) can exist together with increased molecular concentration of the blood, and that it is not justifiable in cases in which a lesion of one kidney can be proved, to conclude that the other organ is also diseased, because the molecular concentration of the blood is raised.

SURGERY.

Nerve Blocking to Prevent Amputation Shock.—It has been claimed that shock in major amputations could, to a large extent, be avoided by the cocainization of nerve trunks previous to their division. For, as stated by Cushing, this injection prevents the conduct of those impulses resulting from the trau-

matic insult which otherwise, by acting reflexly through the medullary centers, might become the chief factors in the production of shock. H. B. Gessner (*Am. Med.*, Sept. 24, 1904) reports two successful cases in which this method was tried. The first patient was a man suffering with tuberculosis of the right knee and femur, with partial anchylosis. Amputation was decided on through the middle of the thigh and as the posterior flap was being made, the great sciatic nerve was identified. This was infiltrated with 25 mg. of a two per cent. solution of cocaine hydrochlorate, and then divided at the same level. After the amputation was completed, the great sciatic and internal saphenous nerves were injected in similar manner on being drawn out for shortening. The pulse fell from 80 to 62 when the operation was finished. The other operation was performed for condrosarcoma of the right tibia. In this instance only a one per cent. solution was employed with equally good results. There was a later rise in pulse which may have been due to "delayed shock." In neither case did the blocking have any bad effects, and the time required ought to be less than five minutes.

The Iodine Treatment of Suppuration.—Excellent results in the treatment of this condition have been attained by W. S. Pugh (*Am. Med.*, October 15, 1904), who has used in a variety of cases and calls attention to the cheapness and other good qualities of the drug when compared with the many antiseptic preparations on the market. Scalp wounds, which are usually dirty, can be cleaned with normal saline solution and then dried. After being swabbed out with iodine, they may be sutured and good union will usually be obtained. In ulcers of the leg it acts as a germicide and a deodorant, stimulates the formation of granulations, and, even in the case of large ulcers, promotes healing when combined with rest in bed. Inguinal adenitis was treated by free incision, the pus swabbed by means of dry sponges and then the iodine applied to every part of the wound. Where suppuration was not too extensive, closure of the wound with hoops of union by first intention was tried, and with success in many cases. Upon vaginal discharges, particularly those due to the gonococcus, iodine exerts a favorable influence. The discharge ceases in many cases, after a few swabbings. Old tuberculous sinuses following upon tuberculous glands of the neck are very favorably affected and in a number of other surgical conditions it will be found of great value and should always be tried.

Suture Material.—While the field of surgical pathology, bacteriology, and physiology has been widely extended, the more technical aspects have been neglected during recent years, according to v. Mikulicz (*Deut. med. Woch.*, September 29, 1904). Silk and vegetable fibers are the most prone to give rise to wound infection in places where the entire absence of germs from the wounds cannot be guaranteed. Metal wire is strong, lasting and antiseptic, but cannot well be used for buried sutures. Silkworm gut presents similar characteristics. Catgut and other animal sutures can be made perfectly aseptic, but they are too rapidly absorbed. The author suggests the use of tanned catgut, which is prepared as follows: The strands are wound on glass plates and then immersed for twenty-four hours in a five per cent. aqueous infusion of quebracho bark. Sterilization is done by the Hofmeister method. By this treatment the material gains in tensile strength and its absorption is delayed for at least four weeks, although the process may not be complete for eighty to ninety days. The author has used this material for abdominal sutures after gastric and intestinal operations, and found it very satisfactory.

PATHOLOGY AND BACTERIOLOGY.

Rhinophyma.—The extraordinary tumors, which occasionally develop upon the nose, are matters of interest from a clinical standpoint and more particularly from the pathological. G. W. Wende and Charles A. Bentz (*Jour. of Cut. Dis.*, October, 1904) report the pathological analysis of five separate tumors occurring in the same patient. The pathological condition presented occurred in a man sixty-nine years old, of German parentage, who had lived in the United States forty years. An excellent photograph of the lesion portrays the tumor as extending from the tip of the nose downward, across the mouth to the center of the chin. He refused to have any investigation practised, because he believed the presence of the tumor prevented him from incurring other infections. The measurements were as follows: Largest diameter from the base, 4¾ inches; transversely, 3¼ inches; at right angles with the face, three inches. In addition to this large one, there were eight smaller tumors on the nose, the the larger of which were pedunculated so as to oscillate freely when the head moved. There was an atrophy of the epidermal layer of the skin over the tumor, the outer layer having disappeared. Huge comedones obstructed many dilated granular orifices. These would refill gradually and discharge the foulest matter. The patient refused treatment until he passed into a comatose condition, when Dr. Bentz made the following notes: Indurated mass between zyphoid and naval, mass painful on palpation, probably hepatic cirrhosis. Five of the nine tumors on the nose were removed including the greatest, which was about twenty-five years old, and the most recent, which had developed only six months before death. The section of these tumors formed an invaluable means of following the history of their development. A most striking change was the enlargement of the sebaceous glands. This was due to the formation of retention cysts. The other marked feature of the case was the extraordinary connective tissue hypertrophy. No mast cells were found, but micrococci and bacilli were plentiful, the latter simulating those described by Gilchrist as occurring in acne vulgaris. Sections of the second smallest tumor stained with osmic acid showed that the epidermis had undergone passive changes, due to an admixture of fat; it was about twice its normal thickness. The pigment of the rete was greatly increased and the horny layer was very much thickened. The sections stained widely on osmic acid, showing that a large part of the increase in size was due to fat. The term adenoma cannot properly be applied to these tumors, because there is no numerical increase. The development of the growths seems to have been dependent very largely upon a dilatation of the ducts of the sebaceous glands combined with extensive fibrous tissue proliferation. The *Demodex folliculorum* was not especially searched for, although short thick bacilli in large numbers were invariably seen in the glandular ducts.

Size of Urinary Stones in Egypt.—There is no question that the Nile country is the home of urinary concretions. Frank Milton (*Lancet*, October 1,

1904) reports the history of 159 cases of stones weighing 50 grams and over. His associate, H. M. N. Milton, operated on 113 of these. They are consecutive cases and altogether unselected. All the patients were over fifteen years of age with the exception of nine. The largest stone weighed 995 grams. The largest stones treated as indicated were as follows: By lithotrity, 452 grams; by suprapubic lithotomy, 292 grams; by perineal lithotrity, 387 grams; by left lateral lithotomy, 90 grams. The results were as follows: Lithotrity cases, 84, deaths five, mortality 5.9 per cent. Perineal lithotrity cases, 47, deaths seven, mortality 14.9 per cent. Suprapubic lithotomy cases, 22, deaths 8, mortality 36.3 per cent. Left lateral lithotomy cases, 6, no deaths. The mortality for the cutting operations was 18.9 per cent. For the crushing operations 5.9 per cent. The size of the stone is a very important factor since a patient with a large stone almost invariably has secondary degeneration of the kidneys. The English operators in Egypt are very much in favor of the crushing operation, although they admit that its success depends very largely upon the experience and skill of the operator. It is a mistake to believe that the Egyptian stones are frequently very soft and that they bear a relation at all constant to chyluria. It is true that the soft phosphatic stones do occur in Egypt. Of the 159 cases, not one had chyluria.

Case of Banti's Disease.—Very little is known of the pathology of hepatic cirrhosis with splenic enlargement, the complex set of symptoms, which have been designated Banti's disease. J. F. Strick and J. F. Hodgson and W. B. Anderson (Lancet, October 1, 1904) gave a very detailed history of a case occurring in a married woman, forty-six years old. She had a fall which had produced severe epistaxis. There were profound anemia and a prominent abdomen. The woman believed that at the time of her recent confinement everything had not been taken out of her uterus, and in this manner accounted for the swelling. There had been an unusual amount of liquor amonii and the midwife had said that the baby was drowned in it. There was no sign of syphilis, she having had eleven children with no miscarriages. The skin was shriveled; had no red tint and resembled that seen in malignant cachexia. Pigmentation, however, was marked. Atrophy of every tissue had taken place, so that she was reduced to skin and bone. The spleen, which was immensely prominent, was tender to the touch. It almost touched Poupart's ligament. Its surface was smooth and its consistence firm. The liver was only slightly enlarged, but it was tender. There was no ascites or edema anywhere. The glands were not enlarged. She suffered from no cardiac palpitation. The pulse was weak, soft and varied from 100 to 110. There were 2,380,000 red cells, 4,640 white, the hemoglobin being 36 per cent. The reds were normal. Melena occurred only a few times. Several days before death, her blood showed red cells 1,140,000, leucocytes 3,200, hemoglobin 20 per cent., poikilocytosis marked. She died just five years after the splenic enlargement had been found. Post mortem showed 32 pints of fluid in the abdomen. The spleen was fourteen inches long, 8 inches across and weighed 9 pounds. It was red in color and the fibrous tissue markedly increased. There were patches of cicatricial tissue which looked like infarcts. The capsule was markedly thickened, the liver enlarged, yellowish-brown and smooth. The stomach wall showed no lesions. Bacteriological examinations of the blood taken anti mortem were negative. The microscopical findings of the spleen showed enormous overgrowth of fibrous tissue. The Malpighian bodies were diminished in number and size. Very few red corpuscles were seen. There was much pigmentary degeneration throughout. The liver was also characterized by immense fibrous tissue proliferation. The lobules were, however, not constricted by it, but were rather disorganized, for the proliferation was intercellular. The bile ducts were normal as well as the hepatic arteries. In neither spleen nor liver was there any reaction with iodine or methyl violent. No bacteria were found.

Experimentally Produced Epithelial Metaplasia in the Stomach.—The results of experiments in rabbits and the relations of epithelial metaplasia to carcinoma, as demonstrated by cases reported in the literature, are discussed by G. Futterer (*Jour. Am. Med. Ass'n*, October 15, 1904). The rabbit experiments were undertaken for the purpose of studying the relations between mechanical irritation and the development of carcinoma. In a series of experiments on the stomachs of 94 rabbits, a genuine epithelial metaplasia was found in five. In each case a piece of mucous membrane of the stomach was resected and, subsequently, hypodermic injections of a solution of pyrogallic acid made to reduce the percentage of hemoglobin and thus prevent the healing of the defect, the edges of which were exposed to friction by solid food. The animals were killed at varying periods, but many animals had died owing to improper care. The five cases in which examinations showed metaplasia, the latter were undoubtedly genuine epithelial, as an ingrowth, an implantation and a development from a germinal deposit could be excluded. There was no fistula in any of the cases. In all cases the metaplasia was at once followed by a downgrowth. The latter has occurred under considerable growth pressure, as shown by the invagination of the muscularis mucosæ through the greater part of the hypertrophic muscularis propria, and the invagination of the rest of that layer for quite a distance outside that organ. The metaplasia has been followed by what may be termed a practically unlimited proliferation of the squamous cells. Such a downgrowth and an unlimited proliferation of cells are the two principal characteristics of carcinoma. The term metaplasia can only be used here for the metamorphosis of the columnar into the squamous cells, for there is no more metaplasia going on in the pegs, the products of metaplasia. The epithelial cells have nowhere broken through the muscularis mucosa, and the most characteristic peculiarity of carcinoma, the ingrowth into connective tissue, is absent. What would have become of the strands, filled up to the very end with squamous epithelial cells, if the animal had lived longer, cannot be said and further experiments cannot show it. These are the first cases of epithelial metaplasia on record, if a metaplasia in the bladder, which Lubarsch mentions without describing, may be excepted. It is to be remembered that structures considered to be characteristic of the ectoderm have been produced from entodermal tissues, a fact which would make it impossible to uphold a sharp division of the germinal layers. The cases which have been reported, concludes the author, make it clear that epithelial metaplasia is very often followed by the development of a carcinoma, but what the real relations are between

metaplasia and carcinoma is a matter that only can be made clear by further experimental work.

THERAPEUTICS.

Therapeutics of Gout.—Robin (*Bull. gen. d. therap.*, No. 16) discusses three types: (1) The acute attack of gout; (2) subacute gout; (3) chronic gout. Colchicum and its active principles is the chief drug. Granules of colchicine, 0.001 gram—four granules at the onset, or during twenty-four hours. Tincture of the seed or root is effective, but variable in strength. To obtain results, 40 to 60 drops a day in doses of 10 to 15 drops at a time is necessary, if a visceral manifestation preceded the articular attack or venal symptoms. The action of colchicum can be aided by local applications, and hot air or steam. Sodium salicylate is useful in subacute gout. In chronic gout, hygiene, regulation of life and drugs are all equally important. In diet, red meats should be excluded. But two-thirds of the diet should be made up from white meats. Of drugs, strychnine and arsenic are valuable.

Treatment of Constipation by Olive Oil.—Kussmaul introduced the injection of olive oil for the treatment of constipation a great many years ago, but the value of the procedure has not been recognized either in England or America. George Hershell (*Lancet*, October 1, 1904) states that while without question it is most valuable in the treatment of cases due to spasmodic conditions, he has found that the methodical use of oil injections, is one of the best means of treating mucomembranous colitis. For some unknown reason it serves to reduce the amount of mucus in a very rapid and satisfactory manner. A third indication for its use is in intestinal atony, which is being treated by electricity. All purgatives should be abandoned and during the first week it is well to remember that there is apt to be a great deal of trouble because the newly inaugurated electrical treatment has not yet become effective. The author injects from three to ten ounces of warm olive oil into the rectum at bedtime. This is retained during the night and usually gives a satisfactory result in the morning. It is important that the oil should be introduced very slowly; otherwise it will be at once expelled. To this end it should be given by means of gravity and not with any form of bulb syringe. A rubber douche bag should of course not be used, but a glass one, and it should be raised only just high enough to allow the oil to flow. It is noteworthy that the nozzle should have an opening in it much larger than that usually employed in aqueous enemata, otherwise it will be blocked by the oil.

Gersuny's Method in Ozenatous Atrophic Rhinitis.—Most rhinologists accept the theory of Taufal, that ozena is due to the length of the nasal cavity in consequence of a defective development of the turbinated bones, this having taken place in such a manner that the mucus is not able to be gradually expelled forward as under normal conditions. This settles on the walls, obstructs the cavity, then dries and becomes putrid. Gersuny, of Vienna, in 1900, published a new method of prothesis, by means of injecting melted vaselin in the tissues, others undertook to build up the atrophied turbinated bones by the use of paraffin. A certain amount of elasticity is essential to the mucous membrane covering the bones to successful operation. This is best determined by the use of a solution of adrenalin applied to the mucous membrane, and any diminution in volume noted. L. Guarnaccia (*Arch. Inter. de Lary. d'Otol. et de Rhin.*, July-August, 1904), maintains that in all operable cases a disappearance of the most objectionable symptom, viz., the fetid odor, takes place, also an amelioration of the other symptoms, and at times a complete cure. His technic is to employ paraffinated vaselin, which has a melting point of 45° C., sterilized by placing in a kaolin capsule at a temperature of 100° C., for half an hour. The nasal fossæ are cleaned of crusts by tepid formalin ½ per cent., and the use of absorbent cotton soaked in hydrogen peroxide. Because of the artificial resistance caused by the vascular constriction following the use of cocaine and the very slight discomfort caused by the operation, its use is best omitted. A Pravaz syringe holding 2 c.c. with a straight needle 4.5 cm. in length is employed. For a few minutes previous to the operation, the syringe, filled with vaselin, is kept in water at a temperature of 46° to 48° C. By the aid of a large Duplay speculum the reconstruction of the turbinated bones should be begun by introducing the needle at an angle of 40 degrees into the posterior third. Directly after the removal of the needle an absorbent cotton tampon soaked in cold sterilized water should be applied to the nares. This operation should not be oftener than once a week. To completely modify one turbinated 4 to 6 gms. are necessary. The bad effects claimed by many seem due to too large an amount injected at one time, or to the high temperature employed.

Treatment of Medical Hemorrhage.—Medical hemorrhage has been defined as bleeding, which has occurred at a site where hemostatic forceps cannot be applied. Francis Hare (*Lancet*, October 1, 1904) gives a further history of cases of hemoptysis in which the bleeding has been stopped almost instantly by amyl nitrite. He had already commented favorably upon the method in the *Lancet*, August 20, 1904. Thirteen cases, therefore, are brought under consideration with the following conclusions: Twelve ceased within three minutes, the thirteenth having continued to bleed for ten minutes. These were all cases of hemoptysis and the nitrate was given by inhalation. It certainly can do no harm to break a pearl under the nose of a patient suffering from this form of medical hemorrhage, and if this rather insufficient report is to be allowed to give weight, the treatment may be considered capable of much good. The drug acts, as pointed out by the author, by suddenly lowering the peripheral resistance in the systemic arterioles, thus reducing the blood pressure in the pulmonary circulation indirectly through the fall of blood pressure in the left auricle. It is a singular fact that in these thirteen cases, there has been no recurrence of the hemoptysis. This is the more singular when one considers that the action of the drug is extremely evanescent. In but one case did the hemorrhage occur within two hours, and in half of the cases there was no recurrence. It would seem that the period of time during which there is a diminished arterial pressure is sufficiently long for coagulation to become well established. Arguing by analogy, it becomes obvious that in the absence of amyl nitrite, plunging the patient into a very hot bath, would have the same effect. The mouth and nose should be protected from inhalation of the hot air, indeed cold inhalations should be given, if possible. By a reversal of the processes which caused asthmatic dyspnea, migraine and metrorrhagia, these processes should theoretically, at any rate, be limited or entirely abated.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, NOVEMBER 12, 1904.

SANITARY ASPECTS OF THE RAPID TRANSIT SUBWAY.

To the people of New York City the opening of the Rapid Transit Subway, on October 27, was an event of the greatest interest. It was the beginning of a new method of transportation in a city where ordinary transportation facilities had failed utterly to carry the people with speed, comfort or decency. It has been said that we are entering upon an era of tunnel building, and that if the present sample of subway proves as successful as expected it will be only a question of time before every important avenue in Manhattan will be undermined and tunnels will run under the harbors and rivers to every outlying section of the city. At the prospect of so vast a development of underground travel it is natural that the public should scrutinize with more than ordinary curiosity the section of road already built. The section is large enough, and has now been in operation long enough, to give a popular idea of what the rest is likely to be. In a strict sense the road is on trial. The public is the judge. Approval means patronage and a generous patronage means building of more roads.

At the present moment public interest in the subway seems to be focused upon the question: "Is it sanitary? Is this newest form of travel free from conditions which may injure the public's health?" New York has had about two weeks of opportunity to judge of conditions as they are and will be in the new subway. There are, of course, certain improvements that will surely take place to ameliorate minor inconveniences. The sanitary conditions, however, are probably at least as good now as they will ever be, for with the collection of dust and dirt in the lapse of time, hygienic conditions will rather deteriorate than improve.

Apparently the chief concern of those who are anxious about the salubrity of the subway relates to the quality of the air. A considerable amount of dissatisfaction is being expressed with respect to the ventilation. Letters of criticism appear daily in the public press, in which patrons of the road point to various fancied causes of alarm. It is said that the air of the subway is warm and damp, and, consequently, ideal for the existence and propagation of bacteria; that the principal agencies which make way with disease germs in the streets, sunshine and rain, are not compensated for by adequate provision for scrubbing, flushing and disinfecting in the subway, except at the stations; that disagreeable odors, heat and dampness, not to speak of unpleasant physical symptoms, such as depression, headache, nausea, accelerated respiration and giddiness occur and show that the air is not renewed with sufficient frequency. That the introduction of fresh air through the piston action of the trains is impossible on a four-track road; that the cars represent the most primitive construction so far as ventilation is concerned; that the oxygen in the air is sometimes as low as 11 per cent., instead of being about 20 per cent. as it should be; that the amount of fresh air in some of the deeper sections is so small that an accident which would delay a crowded express for a half hour would result in wholesale suffocation, etc.

As to the justice and injustice of many of these criticisms there is thus far no official or material proof. Undoubtedly the air in the subway is stuffy, and has been warmer and damper than the air outside in the period since the road was opened, and it has often been unpleasantly close in the cars. That extremely sensitive persons and those in delicate health may be disagreeably affected by these conditions, as well as by the odors of oil and paint, which have prevailed, there is no room to doubt, but such sensations as have been experienced might equally well be attributed

to the suffocating sense which comes to many people when they know they are underground.

If it be proven that there is a marked reduction in the amount of oxygen, distinctly serious conditions may be developed, for it is believed that diminished oxygen, sudden changes in pressure, of moisture and of temperature in the inspired air, all lead to respiratory difficulties. With the present increase in the incidence of pneumonia, it is not an encouraging prospect to find that just where New Yorkers are likely to be crowded together, there is a dangerous accessory condition for the production of this dread disease.

There are certain features of the new mode of rapid transit that cannot but appeal to the modern sanitarian. The complete absence of sunlight removes one of nature's best safeguards against the undue multiplication of bacteria. Direct sunlight is the best bactericide that we have. In the comparatively warm, moist air of the subway, bacteria of disease are likely to live much longer than they would in the upper outer air. The question of cleanliness then becomes extremely important, and if serious danger from the spread of infectious disease is to be avoided, the cars must be frequently disinfected and must be exposed every day for many hours to the direct effect of sunlight in the open air.

It seems especially unfortunate, in the light of this danger from dirt, that the introduction of a feature of a subway-station decoration not originally included in the plan, and which has only been called to public attention since the formal opening of the tunnel, should have been permitted. We refer to the advertising signs at the stations. The stations were magnificently built for the ready and effective maintenance of sanitary conditions. The perfectly smooth tiling, the deliberate absence of ornamentation of any kind that would invite the clinging of dust particles, the rounded corners that facilitate thorough cleansing, all remind one of the modern hospital in a way that is most gratifying. Now comes the unfortunate introduction of a series of advertising signs, made in such a way as almost to invite collections of dust in and around and behind them.

The medical visitor of the days before the regular opening of the subway had happy visions of the easy methods by which stations could be washed out in every part with a hose and the more uncleanly portions rendered hygienic by means of a bucket and mop; but now there is an end of any such prospect. It will be absolutely impossible to clean in and around these signs and they will go on accumulating dust and dirt, which will be raised up into the air at moments when traffic is heaviest, thus rendering the inevitably insanitary conditions of any continuous tunnel railroad even more dangerous than they were before.

Attention to matters of personal hygiene demand equal attention. The vice of spitting must be vigorously rooted out, and the further vitiation of the air by the fumes of tobacco should not be permitted.

The question of the sanitary condition of the subway, now that the subject has become a matter of serious question, should be taken up and studied thoroughly as its weight and bearing demand. The subject is far too important to be left in the realm of conjecture any longer. The interests of the public, of the Rapid Transit Commission and the Interurban Company require that idle speculation should cease and that the facts about the ventilation and the probability of spreading infectious diseases in the subway should be set at rest.

There is only one way to get at the truth and this is by means of a thorough and careful investigation. Experts should be called, if necessary, who have a recognized skill in the use of analytical apparatus and whose business it is to investigate and prevent the spread of disease. These observations should cover all sections of the road and all conditions of travel. The different effects produced by different conditions of weather should not be overlooked.

It would seem that the Department of Health could apparently undertake such an investigation and that a periodic examination of the subway, including sanitary inspectors and analysis of the air, would form a valuable addition to its regular routine work. If, for any reason, the investigation could not properly be made by the Department of Health, it should be undertaken by the Rapid Transit Commission itself. The Commission has ample means for such a study and the results would very likely produce data which would prove of value in its future work.

"DON'T YOU HEAR THE BABY CRY?"

Class legislation is always a difficult matter to attempt, but a little trifle like that would hardly ruffle the serenity of the good dames of Massachusetts, for these most estimable matrons of the old Bay State have been prominent in good works from the time in which they alighted from

their flying broom-handles to deliver their attenuated bodies to the blazing stake up to the present epoch, when their baked beans, fishballs and brown bread have done so much to enliven the murky gloom of the New England Sabbath.

Virtuous and intolerant they have always been; full of good points, which they have invariably insisted in sticking into other people, until the shoulder of Hester Prynne glowed with the scarlet letter of their burning disapproval and Skipper Ireson was tarred and feathered and carried in a cart by the women of Marblehead. But never until this hour have they, as a class, been accused of originality, or have they deviated from the immutable customs of their ancestors, either in the receipt for their doughnuts or in their blind adherence to the bigoted dogmas of the past. Now, however, we learn that a number of women, who have been prominently identified with movements of all kinds for the improvement of the condition of their sex, have incorporated in Massachusetts an insurance company with the avowed object of encouraging maternity by the paying to policyholders of a premium on the birth of children. The scheme is not only new, but is mathematical. Thus the bride with expectations pays $3 monthly assessments. After ten of these monthly assessed payments, which amount, with the initiation fee, to $34, have been made, the assured is entitled to claim a cash payment of $200 on the birth of a living child. If she neglects her opportunities until after the nineteenth payment has been settled she is entitled to $300, which sum increases to $400 after the twenty-eighth, while at any time after the thirty-seventh she can demand a royalty of $500, C. O. D.

Exactly on what plan the arithmetical part of this project is based we do not know. We are not practical actuaries, but it strikes us that unless those eligible have the courage of their convictions in regard to quick sales and small profits, that they would hardly care to enter the pool, and if they did, it is a question if the amount of money on the proposed basis of assessment would hold out to a degree sufficient to meet the obligations. All these schemes, however, seem to belong to those matters that they order better in France. For, this giving of prizes for children while-you-wait and the bonus for large families, is much more adapted to Gaston and Alphonse than it is to Ichabod and Praise-God-bare-bones, and the number of bills looking to the increase of the birth-rate, already introduced into the French Chamber of Deputies, seems to be even greater than the increase of the population itself. Thus one legislator proposes the offering of prizes for large families and the remission of taxes to the happy fathers of many sons. Another interesting suggestion is, that unmarried men shall be ineligible for official positions under the government or municipalities, while the latest bill introduced provides that married men and the fathers of children shall be exempt from military service, and that the French army shall be limited to bachelors only.

The conditions, however, are somewhat different in this country, particularly in the New England States. It has always been claimed that the peasant women of France hoard their money in an old stocking, and the same may be true here, particularly in the seaport towns, the only difference being that in the American case the stocking is invariably a new one. But the "*dot*" is not with us a required stipulation in the marriage contract, and some other reason than a want of money must be found to account for the great preponderance of unmarried women in these rural Eastern communities. According to the last census the unmarried woman comprises 37.4 per cent. of the female population in Massachusetts, while the expression "a Lynn couple," denoting two women and one man, is older than the first census itself, it having, it is believed, originated from the personal observations of Governor Winthrop when he took his English boots to be resoled in that colonial shoe-making center.

What the reason may be for the existence of so many sad, ungathered roses on the New England ancestral tree, it is hard to say. If, as we have been taught, marriages are made in Heaven, then the Massachusetts delegation to the celestial regions must surely have neglected the interests of their fair constituents and have been guilty of "loafing around the throne" to a degree that is more than culpable. For it is here that, after all, the key to the solution really lies. If these worthy, but unpractical, colonial dames would only give up their visionary ideas of paying for their future population on the instalment plan, and remembering the advice of the Hon. Timothy Campbell in regard to the "gondolas," would only seek to marry off these spinsters and then "let nature take its course," they would not have to look in the columns of old *Advertisers* for the names which have been so long historic in that good commonwealth. Let them keep on, and they will, with their Dorcas societies: let them send letters of instruction to the fathers, and flannels

to the mothers, for, anything that will serve to keep alive the babies that have been born will also serve to maintain the population beyond the mere counting of the chickens that are already hatched. Let them instruct young mothers how to take care of their children, how to feed them, how to clothe them, and how to nurse them in sickness, as the death-rate among infants is now abnormally high, but do not let them forget that the curve of old-maidism is also steadily increasing, and that the time has come when some active legislation must be taken in the spinster interests.

What this is to be or what course it may take it is difficult to say. The time has passed when a thousand or two Sabine youths could be injected into the social veins of Massachusetts and it might not be possible to de-Corbin-ize the National Guard, but a State that can successfully raise two such utterly different products as Harvard College and J. Laurence Sullivan has more than enough versatility to accomplish this, or, in fact, anything. The autumnal fruit of New England, too, should not be a difficult crop to market. Strong, energetic, capable, a good housewife, a woman in fact possessed of all the virtues of domesticity, she should not be left to waste her sweetness on the ocean air. Those provincial heirlooms, the feather beds of Massachusetts, made with the live feathers of her native geese, are traditionally soft and warm; the nights on the stern and rock-bound coast are proverbially drear and long; let these good women, with their irrepressible desire to be the ladies of creation, see that the dear *old maid* is no longer left "out in the cold—alone."

ECHOES AND NEWS.

NEW YORK.

Japanese Medical Corps.—Dr. Louis Livingston Seaman, late Major U. S. Volunteer Engineers, delivered an address on his experience while studying the condition of the Japanese Medical Corps during the present war, on Thursday evening, November 10, 1904, at the Calumet Club.

Civil Service Examinations.—The New York State Civil Service Commission announces general examinations to be held December 3, including the following positions: Physician, fourth grade, State hospitals and institutions; resident physician, State industrial school, Rochester. Applications for these examinations must be made on or before November 28. Full particulars of the examination and blank applications may be obtained by addressing the Chief Examiner of the Commission at Albany.

Medical Society of the State of New York.—It is the desire of the Business Committee of the Medical Society of the State of New York to present a good and representative program to the Society at its approaching annual meeting, which comes the last of January at Albany. The Committee, which has already been announced, consists of Drs. Henry Flood, of Elmira, Chairman; A. Edward Davis, of New York; and L. H. Neuman, of Albany, Secretary. The Committee will soon close the program, and before doing so extends an invitation to members and others who may desire to appear upon it to communicate with either member of the Committee soon.

Reorganization of the New York School of Clinical Medicine.—During the past few months there has been a complete reorganization of the New York School of Clinical Medicine, and the following physicians now constitute the Faculty: Professors—*General Medicine*, Drs. Wm. Brewster Clark and Henry L. Shively; *Surgery*, Dr. S. J. Walsh; *Genito-urinary Diseases*, Drs. Wm. K. Otis, Walter Brooks Brouner and John Von Glahn; *Gynecology*, Drs. Augustin H. Goelet and A. Ernest Gallant; *Mental Diseases*, Drs. Emmet C. Dent and J. Arthur Booth; *Dermatology*, Dr. Robert J. Devlin; *Ophthalmology and Otology*, Drs. John L. Adams and George A. Taylor; *Pediatrics*, Drs. Dillon Brown and Henry C. Hazen; *Gastro-intestinal Diseases*, Dr. Robert Coleman Kemp; *Diseases of the Nose and Throat*, Drs. Max J. Schwerd and James S. Waterman; *Orthopedics*, Dr. Homer Gibney; *Pathology*, Dr. E. E. Smith; *Hydrotherapeutics*, Dr. A. W. Gardner. Associate Professors—*General Medicine*, Drs. T. M. Acken and E. L. Kellogg; *Surgery*, Dr. J. Cameron Anderson; *Gastro-intestinal Diseases*, Dr. C. T. Graham-Rogers; *Genito-urinary Diseases*, Drs. T. M. Townsend and Stern; *Pediatrics*, Dr. H. F. Senftner; *Opthalmology and Otology*, Dr. H. E. Cook. A number of instructors and clinical assistants have been appointed, and new appointments will shortly be confirmed. At a recent meeting of the Medical Board, Dr. John L. Adams was elected President; Dr. A. E. Gallant, Vice-President, and Dr. Robert Coleman Kemp, Secretary.

Charities and Correction.—The Fifth New York State Conference of Charities and Correction is to meet at Syracuse, November 15 to 18 next. The conference was organized five years ago by the State Board of Charities, acting in conjunction with representative philanthropic citizens from all parts of the State, and has proved to be a very successful and popular organization. Its objects are to afford an opportunity for those engaged in charitable and reform work to confer respecting their methods, principles of administration and results accomplished; to diffuse reliable information respecting charitable and correctional work, and encourage cooperation in humanitarian efforts, with the aim of further improving the system of charity and correction in the State of New York. To carry out these purposes the conference holds an annual meeting in November of each year. All who have an active interest in the public or the private charitable or correctional work in New York State are invited to enroll themselves as members of the conference and to participate in the discussions and business of the meetings. The public generally is also cordially invited to attend all the meetings of the conference.

Japanese Physicians in New York.—A Japanese imperial medical commission, which has been making a tour of the health departments of the principal cities of this country and Europe, visited the Health Department building at Sixth Avenue and Fifty-fourth Street last week. The commission consists of Dr. Takamine, Professor of Chemistry in the Imperial University at Tokio; Professor Tanva, of the department of pharmacy in the same university, and Dr. Sato, chief sur-

geon at the university. Health Commissioner Darlington personally conducted the Japanese scientists about the building, and explained the workings of his department. Dr. Sato, spokesman for the commission, declared that the department in this city was better than anything he had seen in his tour, with the possible exception of that at Hamburg, Germany. But in Hamburg, he said, the commission is hampered by legal restrictions, that it does not have liberty of action enjoyed by the health officials of New York

Sir Felix Semon and Mount Sinai.—Sir Felix Semon made an inspection of Mount Sinai Hospital last week, and had nothing but words of praise for the institution. Accompanied by Dr. D. Bryson Delavan, the senior attending throat specialist, and Dr. George Leffert», with whom Sir Felix is staying in this city, the English specialist went to the hospital. He was received by Dr. S. S. Goldwater, the Superintendent; F. J. Rieser, the Assistant Superintendent, and the medical staff. Following the inspection Sir Felix said: "This hospital is a tremendous advance over any hospital I have seen. It is the 'acme,' I might say, of hospital perfection. It seems that such accomplishment is only possible in this country, for surely it cannot be done in Europe. You are fortunate in having enormous wealth devoted to such commendable purposes, while we, though we have wealth, unfortunately see it not so commendably applied."

The New Manhattan Eye and Ear Hospital.—The new building of the Manhattan Eye and Ear Hospital, to be erected in Sixty-fourth Street, on a plot of nine lots, just east of Third Avenue, and next door to the Baron de Hirsch Trade School, will be one of the largest, and perhaps the most complete, of the special hospitals of the world. A new structure is needed, as the requirements of the institution have outgrown the accommodations of its present home, at Park Avenue and First Street. In 1903 there were 28,478 outdoor and 2,954 indoor patients; by September 30, 1903, 372,687 patients had been treated since the hospital's incorporation in May, 1869. Plans for the new building, designed by York & Sawyer, have been approved. The cost of the structure will be between $350,000 and $400,000. Ground will be broken before December 1, and it is hoped to complete the building within fourteen months. The edifice will have a frontage of 118 feet and a depth of 125 feet. It will be five stories high. The ground and first floors are given up to the clinics for dispensary work. At the rear of a general waiting room, under a skylight, the superintendent, or one of his assistants, will stand, to sort the clinic patients. All of the first floor other than the general waiting room is given over to the eye department, the two sides of which contain clinics. The second floor is divided through the center, but, instead of having clinics of the same department upon each side, the eastern part is given up to the nose and throat, while the ear department occupies everything on the right of the large waiting room. In the nose and throat clinics the cabinets are arranged in pairs, set out at right angles to the wall, and furnished with gas, electricity, compressed air and plumbing. Each pair of assistants, who will sit at one of these tables with their patients, will be separated from the others by low partitions. Old patients who have already had their cases diagnosed by surgeons will be seated at once on special benches, each one of which has appended the name of the assistant to whom they were assigned at their last visit. Orderlies will keep run of the number of patients waiting for the surgeon and his assistants, and show them in in rotation. Ear clinics are of much the same arrangement, but have in addition ear-testing rooms, which are isolated for sound, and have a range of 25 feet.

Eastern Medical Society.—The Section on Pediatrics of the Eastern Medical Society will meet on Thursday, November 17, at 8.30 P.M., at Clinton Hall, 151-153 Clinton Street. Program: Presentation of Cases; Paper, Chorea-Clinical and Therapeutic Data, by Henry W. Berg, M.D. Discussion by Dr. Joseph E. Winters, Dr. E. D. Fisher, Dr. H. D. Chapin, Dr. Henry Koplik, Dr. Wm. M. Leszynsky, and others.

County Medical Association.—The next regular meeting of the County Medical Association will be held at the Academy of Medicine, November 21, 1904. The following interesting program is provided: (1) Paper: Dangers of the X-ray, by Milton Franklin, M.D. Discussion by Drs. Morton, Albers, Coley. (2) Paper: Medical and Surgical Features of the Russo-Japanese War, by Louis L. Seaman, M.D., Major, U. S. Volunteers. Discussion by Surgeon-general Wyman, Capt. Kerouski and other medical officers.

PHILADELPHIA.

Sanatorium Opposed.—Residents of Mount Airy have petitioned the courts to declare the Dermady Consumption Sanatorium a nuisance and order its removal. The petitioners consider the institution dangerous and also declare that the inhabitants of the tents move about with so little clothing on at times as to amount to a disgrace. Twenty patients are now in the institution.

Oil Plant Injurious to Health.—Numerous suits have been brought by the inhabitants of Marcus Hook against the Sun Oil Company whose plant is said to be injurious to health and also damaging to property. The first suit has been decided by a jury in favor of the plaintiff, a verdict for $1,050 being rendered as damages. More than 200 witnesses were called, 135 testifying for the company that the fumes were not injurious and 70 for the plaintiff that they were. A jury from the United States Circuit Court has since inspected the plant in connection with other cases pending.

Address by Dr. Wiley.—Dr. H. W. Wiley, Chief of the Bureau of Chemistry in the United States Agricultural Department, addressed the Franklin Institute, November 4, on the results of the recent investigations regarding food preservatives. Dr. Wiley said that though most experts regard borax and boric acid as the least harmful of the preservatives commonly employed, the truth of this view must be determined by future experiments. The work already done shows that the miscellaneous and premeditated use of these antiseptics in food is reprehensible. "It is evident that eating small quantities of borax in food, occasionally, would not prove of any lasting injury to the ordinary citizen in good health, but the weak and feeble must be protected, and it is entirely with the grounds of reason that even a very small quantity of an antiseptic of this kind would prove very harmful to a disordered stomach. Similar experiments have been conducted with salicylic, benzoic and sulphurous acids, but the results have not yet been compiled nor have conclusions been drawn. This work is to be continued during the coming year, when it is our purpose to determine the effects of formaldehyde and coloring matter, when added to food, upon health and digestion."

Episcopal Hospital.—Dr. Richard H. Harte has resigned as attending surgeon. The vacancy on the staff will be filled by the Board on November 24.

Increased Help for Health Department.—Councils' committee on Health and Charities has recommended the creation of 18 new berths in the Health Department at salaries aggregating $12,000. The salary of Dr. Hawkes, physician in charge of the insane department of the Philadelphia Hospital, is asked to be made $1,500 instead of $1,000. New fire escapes, fire towers and stairways are to be added to this hospital. The sum of $10,000 is also recommended for the purchase of modern hospital beds.

College of Physicians.—At the meeting held November 2, the minority committee on sites presented their report on the location for the proposed new building of the college. This committee has from the start been dissatisfied with the lot already purchased at Twenty-second and Ludlow streets. After a long discussion of the report the following resolution was almost unanimously adopted: Resolved, that at the present time it is deemed inadvisable for this body to erect a building at the corner of Twenty-second and Ludlow streets. Three other possible sites were discussed. These are at Eighteenth above Spruce; Locust, east of Fifteenth Street, and the present site. A report on these sites will be made at the December meeting.

Special Lectures for County Medical Society.—In pursuance of the suggestion made last winter, the Philadelphia County Medical Society will inaugurate a course of special lectures on November 16. Dr. George McClellan will speak on "The Relations of Anatomy to the Needs of the General Practitioner of Medicine," and Dr. Albert P. Brubaker on "The Nervous Mechanism of the Heart-beat." The lectures are free to the profession though primarily intended for the benefit of the members of the society.

Dr. Cullen Addresses Society.—Dr. Thomas S. Cullen, of Baltimore, by invitation addressed the North Branch of the Philadelphia County Medical Society on November 10, taking as his subject "The Causes of Uterine Hemorrhage." The discussion was opened by Dr. Wilmer Krusen.

University of Pennsylvania Medical Society.—At the meeting of October 28, the following officers were elected: President, Dr. C. H. Frazier; Vice-Presidents, Drs. A. O. J. Kelly and H. D. Jump; Secretary, Dr. H. C. Wood, Jr. Five meetings a year are to be held, in November, January, February, March and April.

Artificial Anus in Typhoid Perforation.—At the Philadelphia Academy of Surgery, November 7, Dr. J. Chalmers DaCosta reported a case of typhoid perforation treated by making an artificial anus, this being the only recovery among the five cases of typhoid perforation he has operated upon. The perforated ulcer was two feet above the ileocecal valve and between these points were many ulcers on the verge of rupture. The condition of the patient was desperate and an anus was formed by Bodine's colostomy. The symptoms of typhoid promptly disappeared but ten days later violent pain in the right iliac region was followed by the escape of fecal matter along the outside of the proximal part of the bowel. This was probably due to a second perforation. The patient has now recovered from resection and lateral anastomosis to cure the artificial anus. Dr. DaCosta concludes that in exceptional, and only exceptional, cases of typhoid perforation, the formation of an artificial anus is advisable.

CHICAGO.

Chicago Men Win Medal.—A gold medal has been awarded to Dr. A. J. Ochsner and Meyer J. Sturm, architect, for hospital plans exhibited at St. Louis. The notification has been received from the president of the superior jury. The plans were entered under charities and corrections, Class 139, and consist of complete plans of four hospitals—a city hospital, a country hospital, a hospital for towns, and a hospital for the treatment of contagious diseases. The latter plan presents a radical departure from any existing hospital structures now in use, and it is upon the marked advantages of this building that much honor has been gained. There were fourteen drawings in all. Meyer J. Sturm is assisting architect in the construction of the new Augustana Hospital, and is making a specialty in the matter of hospital construction.

Donation for New Hospital.—The Presbyterian Board of Missions has received a donation from Mrs. Simon Reed, Lake Forest, of $7,000, to be used for the erection of a hospital at Oroomiah, Persia.

State Board of Health Awarded Medal.—A gold medal has been awarded the Illinois State Board of Health for its admirable exhibit in the section of hygiene at the Louisiana Purchase Exposition.

Stenosis of the Lower Portion of the Esophagus.—At a meeting of the Chicago Medical Society, held November 2, Dr. B. W. Sippy presented a man who, five or six weeks ago, began to have difficulty in swallowing. During the act of swallowing he feels great discomfort below the lower portion of the sternum. There is greater discomfort in swallowing liquids than solids. The onset of the trouble was rather sudden. Some days the difficulty in swallowing is greater than it is on other days, and on these days food is regurgitated without any effort at vomiting. The food does not taste sour, but it is practically regurgitated in the same condition as when it is swallowed. He said that when a patient presents himself with pain in the lower portion of the sternum upon eating, and when food regurgitates, or even before the symptom of regurgitation is present, one should suspect esophageal stenosis. There are many things that produce pain on eating, and among them he mentioned obstruction of the esophagus, ulcer of the cardiac end of the stomach, carcinoma of the cardiac end of the stomach, perigastric inflammation, either acute or chronic, perigastric adhesions, epigastric swelling, etc. Dr. Sippy introduced an esophageal bougie of large size and located the obstruction in the esophagus at about forty centimeters from the incisor teeth, the obstruction being near the cardia. A diagnosis of esophageal stenosis at its lower portion was made. After considering at length the differential diagnosis, he said it is advisable to place the esophagus as near at rest as possible. There should be as little irritation of it as possible by giving foods that are mushy in character, neither too hot nor too cold, which will pass readily without causing irritation. Mikulicz, he said, fed a patient through the gastrostomy wound for five years, and still the spasm continued. He subsequently cut down through the gastrostomy wound and forcibly stretched the cardiac orifice, producing a submucous rupture of the fibers, and the patient has had no trouble since. He has operated on three other cases since, with good results. Cases that are recognized early may be so managed that the process does not continue. Spasmodic esophageal stricture may continue for a period of a few months, then followed by spontaneous recovery. But once dilatation occurs, it is very improbable that a patient ever recovers, and

sooner or later there comes a time when there is so much spasm that the patient can no longer obtain a sufficient quantity of food for nourishment. Some cases go on to death in two or three years, while others live many years, but it is a serious condition after dilatation is once present. Dr. Sippy then passed the esophagoscope (having preceded it with thorough cocainization of the esophagus), so that the members could see the point of constriction through the instrument. He said in this case a bougie would be passed day by day; the patient would be given food that was non-irritating; also between thirty and forty grains of bromide of sodium every four hours, and the patient's body would be given as much rest as possible. With this line of treatment he hoped to succeed finally in overcoming the spasm, as there was no ulceration, no erosion, and no sacculation in this case.

Myasthenia Gravis.—Dr. Mortimer Frank read a paper on this subject, saying that it is a rare disease in childhood. Fifty per cent. of the cases have been in the female sex, and between the ages of twenty and thirty years. Only three cases have been reported under the age of ten years. The most important symptoms are ptosis, which was present in over 80 per cent. of all recorded cases; ophthalmoplegia externa, weakness of the muscles of the face, speech, arms and legs. Even more marked than the weakness was the rapid tiring of the muscles on use and upon stimulation by the faradic current. The phenomenon of rapid tiring is usually confined to a few muscles or a group of muscles. Prognosis as regards recovery is practically hopeless. Average duration of the disease from one to three years. Treatment of little benefit. Pathology vague and uncertain. As yet, no characteristic lesions either macroscopic or microscopic. The case reported was in a female child, ten years of age. Ptosis was first noticed in November, 1902. The present condition, bilateral ptosis and external ophthalmoplegia.

CANADA.

Montreal Health Department Annual Report.—The annual report of the Health Department of Montreal for 1903 has just been completed, and it shows that a better system of tabulating deaths and births in that city has been inaugurated. Taking the figure of the population of Montreal as given in the fourth census returns of Canada, completed at the end of April, 1901, by the Federal Government, namely: 267,730 inhabitants, and calculating the probable increase of the city's population up to the middle of the year 1903, the total mortality for the city for that period is 24.39 per 1,000. The mean anual death rate for the past eighteen years, leaving out that for 1885, the year in which the great smallpox epidemic occurred, was 24.77 per 1,000 of the population, while the rate for 1901 was 23.25, and that for 1902 22.58 per 1,000. The rate for 1903 was, therefore, 4.56 less than the mean rate for the preceding eighteen years; 3.04 per 1,000 and 2.37 per 1,000 less than in 1901 and in 1902, respectively. Tuberculosis caused less deaths than in the preeeding years. Before 1900 the number of deaths was 692; in 1901, 647; in 1902, 644; while in 1903 the number was only 633. In 1903 there were two deaths caused by smallpox, or eight less than in 1902; 77 by measles, or seven less than in the preceding year; 24 by scarlatina, or 40 less than in 1902, 21 less than in 1901, and 108 less than in 1900. The deaths from diphtheria and diarrhea cannot be compared, as they have been classified according to the new international system. Under the title "diphtheria" are included the deaths from croup, and under the title "diarrhea," the deaths from enteritis. Typhoid fever caused 90 deaths, or four more than in 1902; but 40 less than in 1901, and 30 less than in 1900. Bronchitis caused 224 deaths, or six more than in 1902. Pneumonia (including bronchopneumonia) caused 528 deaths, or 16 less than in 1902.

Marriage-rate and Birth-rate in Montreal.—It will be seen, according to the annual report of the medical health officer of Montreal, that the mean birth-rate of the 16 past years, without distinction as to nationality, was 39.10 per 1,000 of the population. The French-Canadian birth-rate was 49.95 per 1,000 of population; that of other Catholics, 25.95, and of Protestants, 24.96 per 1,000 for the past sixteen years. The total birth-rate for 1903 was 36.08 per 1,000. The rate for that year among French-Canadians was 43.64 per 1,000: other Catholics, 30.69; Protestants, 20.52. The excess of births over deaths was 3,375, distributed as follows: French-Canadians, 2,541; other Catholics, 337; Protestants, 507. The birth-rate in 1903 was 36.08 per 1,000, or 3.02 per 1,000 less than the average for the preceding sixteen years, and yet it is the highest rate since 1896. It is 0.43 higher per 1,000 than in 1902, and 3.54 per 1,000 higher than in 1901. The report gives the marriage rate for 1903 as 10.16 per 1,000 of the population, giving an increase of 1.18 over the mean rate for the preceding sixteen years, on an increase of 0.94 per 1,000 over the rate in 1902, and 2.01 over that for 1901. The marriage rate among the French-Canadians for 1903 was 10.75 per 1,000 of the population, or 0.79 per 1,000 more than the mean rate for the preceding fifteen years, or 1.04 per 1,000 more than in 1902, and 1.28 per 1,000 more than in 1901. Among other Catholics the rate for 1903 was 7.35 per 1,000, or 1.29 per 1,000 more than the mean rate for the preceding fifteen years, or 0.06 and 1.50 per 1,000 more than in 1902 and 1901, respectively. Among Protestants the marriage rate in 1903 was 10.36 per 1,000, or 1.39 per 1,000 more than the mean rate for the preceding fifteen years, or 1.21 per 1,000 more than in 1902, or 32 more than in 1901.

A New General Hospital for Toronto.—Two of the leading members of the Senate of Toronto University waited upon the Premier and other members of the Ontario Government a few days ago and were successful in obtaining the promise that the Government would contribute $100,000 in the scheme for erecting a new general hospital for Toronto. The Government will provide this sum on the condition that the question of sites, it being understood that it would be donated for the purpose of helping the university in the matter of clinical teaching. It is a question whether the out-patient and emergency hospitals should be located where the other buildings are erected, and in view of the fact that for the former Mr. Cawthra Mulock has already donated $100,000 and another $100,000 has been bequeathed for the emergency branch, it would seem that there may be three buildings to be hereafter called the Toronto General Hospital collectively. It was also a condition of the Government's promise to contribute $100,000 that the City of Toronto would contribute a like sum. These amounts would form a handsome sum with which to commence operations for a very complete and up-to-date hospital. The new hospital, when completed, will form one of the finest in Canada, or on the American continent, and will furnish most complete and satisfactory equipment for the prosecution of clinical teaching in connection with the medical faculty of the provincial university.

Nova Scotia Branch of the British Medical Association.—The annual meeting of the Nova Scotia

Branch of the British Medical Association was held in the city of Halifax, October 5, the election of officers resulting as follows: President, Dr. C. D. Murray; vice-president, Dr. W. H. Hattie; treasurer, Dr. G. M. Campbell; secretary, Dr. E. D. Farrell. Council, Drs. Goodwin, Hattie, Hare, Mader, G. M. Campbell, Mathers and Ross.

A Visitor from Dawson.—Dr. J. N. E. Brown, Secretary of the Gold Territory, Dawson, is spending a six months' leave of absence in Toronto, Ontario, and other points in Canada. Dr. Brown was formerly a practicing physician in Toronto and secretary of the Ontario Medical Association.

Toronto University Senate Elections.—The graduates in medicine of Toronto University have elected the following representatives to the Senate of the University, all of the four gentlemen elected being members of the Medical Faculty thereof: Dr. George A. Bingham, Professor Adam H. Wright, Professor Irving H. Cameron and Professor J. Algernon Temple.

Experts to Examine Montreal's Water.—On account of numerous complaints which have been made for years against the condition of Montreal's water supply, the City Council has appointed a commission of experts to make an exhaustive examination of same. The commission will consist of Dr. R. Ruttna, Professor of Chemistry, McGill University; Dr. A. Bernier, Professor of Bacteriology, Laval University; Dr. J. E. Laberge, chemist, bacteriologist and director of the Montreal Civic Hospital, and Mr. Milton Hersey, chemist and city analyst.

Personals.—Dr. Fred. Harvey has succeeded Dr. Tait McKenzie as director of the McGill gymnasium, the latter having gone to Philadelphia to assume his duties as director of the physical department of the University of Pennsylvania.

The Hon. Dr. M. Sullivan, Professor of Surgery in Queen's Medical College, Kingston, Ontario, has just completed his fiftieth year as a disciple of Æsculapius. Dr. Sullivan started the study of medicine at Queen's in 1854, and is still in harness.

GENERAL.

Alien Asylum Inmates.—A report from the local United States immigration inspectors has been forwarded to Frank P. Sargent, commissioner of immigration, on certain frauds perpetrated by aliens. The Administration has discovered that in nearly every State in the Union a large percentage of the inmates of asylums for orphans and aliens are persons who have been sent to this country especially for the purpose of being placed in such institutions, where the treatment is better than the care given in European institutions. The report deals with institutions in this district. The facts will be presented to Congress. Those who have carefully studied the paper of W. A. White, Superintendent of the Government Hospital for the Insane, can draw the same conclusion from his figures.

Harvard Buildings.—The new Harvard Medical School buildings now in course of construction are so far advanced that a good idea can be obtained as to what the general appearance of the completed group will be. They are situated on Longwood Avenue, Brookline, at one border of the Parkway system surrounding Boston, and are about fifteen minutes' ride on electrics from the present medical school back of the Public Library. The plan is that of a large court, 75-100 yards square, one open and facing on the street, two sides occupied by school buildings proper, and at the head of the court on a raised terrace the administration building. White marble is used throughout, the architecture is simple, and the whole effect when completed will be very beautiful. On the right, facing the court are two buildings for hygiene and pharmacology in one, physiology and physiological chemistry in the other, on the opposite side stand the surgery, bacteriology and pathology building, and next to it one for anatomy, histology and embryology. Work was begun last November, but was considerably delayed by the severe winter. They will doubtless be completed by next summer, and entered the fall of 1905. At present the exterior of all the structures, except that of the administration building, is finished; of the latter, the foundation and part of the framework is completed. Hundreds of men are engaged and work is progressing rapidly. It is the object of the school to have affiliated hospitals near by, and already several institutions at present in the city and anxious to get into new quarters have availed themselves of offers of building sites, on the large tract of land belonging to the University. Work on the new Samaritan Hospital is nearly completed, and preliminary plans have been made for the new Children's Hospital and the Thomas Morgan Rotch Infants' Hospital. Near by, but further in town, is Simmons College, where nurses in some of the hospital training schools of Boston are, or soon will be, taking courses as part of their regular work. Close to this is the new Tufts College building. Further out in Brookline is the Brookline Women's Hospital and the Baptist Hospital, so a nucleus of a large medical center is here rapidly being formed.

Health Drifters.—Under the title of "The Health-Drifters of the Great Southwest," Frank D. Witherbee writes in the current issues of *Charities*, New York, of the great migration of tuberculosis patients to the Salt River Valley of Arizona, and of the life they lead in tents and shacks in and about Phœnix. Out of a winter population of some 15,000, fully 5,000 are health seekers, drawn to Arizona by the dry climate and constant succession of sunny days which are essential for their relief and cure. Fully 90 per cent. of the days in Phœnix are clear and bright, and the relative humidity of the atmosphere is far below that of the average. "On the one hand these conditions lead to a remarkable percentage of recoveries," writes Mr. Witherbee; "but on the other there is an amount of social and spiritual suffering which is not generally understood. As a matter of fact, a great majority of people go too late to be helped by any power on earth. A Phœnix physician has said that fully four-fifths of the visitors are incurable. The streets are filled with them—thin and wretched, homesick and suffering. Heedless physicians and relatives send patients to Phœnix alone and with scant means of support. The blundering argument is made that all the sick one needs is to get to that country and his condition will permit of his doing light work which he can easily find. But the facts are that this incapacitated one is going to a country swarming with people looking for like chances; that it is essentially a ranching community, where the bulk of the workers to be of any service must be able to plow and sow and reap and herd cattle, often standing in water all night long to irrigate. What few chances there are for light work ought not to be accepted because they are too confining. Here, as wherever consumptives have taken up work in desirable climates, they have by their underbidding and their numbers steadily forced wages down to a point where they can scarcely earn enough to live. Many of the necessities of life by reason of high freight rates are much more costly than in other communities. Out on the desert, at the outskirts of the irrigated parts of the valley, and extending to

the foothills, there are tents of all sizes and description. Some are in groups and others stand alone, some are roomy and attractive, others are cramped and desolate looking. Some of the ranchers near Phœnix have made a specialty of providing accommodations for health seekers, and offer furnished tents or rooms in specially constructed houses with board at the ranch house. The local fraternal lodges, the churches, the county almshouse and the one free sanatorium, are crowded to their utmost capacity year in and year out. Many a patient reaches Phœnix with his small capital exhausted by traveling expenses and finds himself dependent upon the resources of a community which has no interest in him and where he finds on many sides an almost hardened indifference to his pitiable need. This is not because residents of Phœnix are lacking in the finer feelings which prompt to charitable service, but because the people of the East and Middle West are, by their lack of forethought, putting upon them a burden which in no sense belongs to them. The supervisors say that he poor in the almshouse cost the county $20,000 a year, and three-quarters of this is spent in the care of ailing consumptives."

Scientific Disposition of Sewage.—In an article in the *Scientific American*, Charles F. Holden tells of the scientific disposition of sewage in the city of Pasadena, Cal. He says: "The sewage plant, consisting of about fifty miles of pipe, has 650 manholes, 140 flush tanks, and all the modern features which go to make up a perfect system, all of which cost the city in the neighborhood of $313,457. The sewer farm is, roughly speaking, about five miles and a half rom Pasadena, and the outfall pipe is about that length, twenty-two inches in diameter and of vitrified clay. It was placed five feet beneath the surface, having a fall of thirty-one and two-thirds feet per mile. There were several features here not found in the East, where rains flush the sewers continually. There was no rain from May to November, hence rain or a natural flow of water could not be depended upon; yet no serious difficulty has been experienced, the natural flow of the waste water being all-sufficient for the purpose. The farm is in the hands of a practical farmer, who runs it on scientific principles, and for nearly a decade it has been a yearly value-increasing asset of the city. The secret of the success of the Pasadena farm method lies in the application of the sewage. Before planting time a horse and plough form several enclosures on the surface to be planted, after the fashion of the long furrow seen in orange irrigation, the idea being to hold the sewage in a location until the fluid permeates the earth thoroughly and completely as would a good rain, that is, to a depth of three or four feet. This accomplished, it is allowed to dry sufficiently for working, when a cultivator is put on, and the ground from twelve to fourteen inches, the deeper the better, thoroughly cultivated and turned over. This is found in the soil at the Pasadena Sewer Farm to not only prepare the ground for the reception of seeds, but to render it perfectly 'sweet,' so there is no disagreeable odor, the hot sun acting as a deodorizer. So thorough is the work of nature after this simple treatment, that the farm managers state that there has never been a case of illness that could be traceable to the sewage or as a result of working in it. A criticism of such irrigation has been made that certain fruits and grasses may carry the impurities, but this is obviated here by an exact system. Thus so complete is the original irrigation that a later application is not necessary, as in the case of pumpkins or squashes."

To Study Epilepsy.—The fourth annual meeting of The National Association for the Study of Epilepsy, etc., will be held in the Medical Library, "The Fenway," Boston, on November 22 next. The Association invites all persons interested in the welfare of epileptics and in charity work generally, to attend this meeting. Among the papers to be read are the following: Presidential Address, by William N. Bullard, M.D., of Boston; The State's Relation to the Epileptic, by Owen Copp, M.D., Executive Officer of the Massachusetts Board of Insanity, Boston; The Prognosis of Epilepsy, by William Aldren Turner, M.D., of London, England; The Influence of Puberty and Adolescence in the Etiology of Epilepsy, by William P. Spratling, M.D., of Sonyea, N. Y.; Certain Aspects of the Differential Diagnosis Between Hysteria and Epilepsy, by Drs. Putnam and Waterman, of Boston; Some Observations on the Treatment of Epilepsy, by Daniel M. Brower, M.D., of Chicago, Ill.; Spectrum Analysis of the Blood in Epilepsy, by J. W. Wherry, M.D., of Clarinda, Iowa; Syphilitic Epilepsy, by Abner Post, M.D., of Boston; (*a*) Observations on Blood Pressure in the Epileptic; (*b*) Lantern Slide Illustrations of Cases, and of the Massachusetts Hospital for Epileptics, by Everett Flood, of Palmer, Mass; Ten Cases on Special Treatment, by Drs. Morton and Green, of Palmer, Mass.; Lumbar Puncture in Status Epilepticus, by Dr. Morton; Senile Epilepsy, by G. Kirby Collier, M.D., of Sonyea, N. Y.

The objects of the Association are: (1) To promote the general welfare of sufferers from epilepsy. (2)To stimulate the study of the causes and the methods of cure of this disease. (3) To advocate the care of epileptics in institutions where they may (*a*) receive a common school education; (*b*) acquire trades; (*c*) be treated by the best medical skill for their malady. (4) To assist the various States in America in making proper provisions for epileptics.

The officers of the Association are: Dr. Wm. N. Bullard, of Boston, President; Wm. P. Letchworth, LL.D., of Portage, N. Y., Vice-President; Prof. Wm. Osler, M.D., of Baltimore, Second Vice-President; Dr. Wm. P. Spratling, of Sonyea, N. Y., Secretary and Treasurer.

CORRESPONDENCE.

OUR LONDON LETTER.

(From our Special Correspondent.)

LONDON, October 29.

ANTITYPHOID INOCULATION—THE PREPARATION OF DIPHTHERIA ANTITOXIN.

SOME eight years ago it was announced that Dr. A. E. Wright, at that time Professor of Pathology in the Army Medical School at Netley, announced that he had succeeded in preparing a serum, the inoculation of which produced immunity in regard to typhoid fever. He first tested it on himself and on some of the medical officers on probation studying at Netley, and later on the nurses and attendants in a large lunatic asylum near Maidstone, at a time when that town was suffering from a severe visitation of enteric fever. Dr. Wright next extended his experiments to troops going to India, where the disease caused a high rate of mortality among young soldiers. The use of the serum was at first sanctioned by the Indian Government, but later the performance of inoculations in India was forbidden by an Army order. Wright was a member of the Commission sent out to investigate the plague in 1898, and

while he was in India he took the opportunity of inoculating some four thousand soldiers in defiance of the order. The results were said to be so good that on the representations of the Principal Medical Officer with the Government of India, official sanction was given to the use of the serum. During the war in South Africa about 100,000 men were inoculated. After the war the medical service of the Army was reorganized, a principal reform being the formation of an Advisory Board composed partly of eminent civilian physicians and surgeons to assist the Secretary of State for War on medical questions. One of the early recommendations of that Board was that the antityphoid inoculation should be discontinued. Dr. Wright appealed against this decision, and the question was referred to the Royal College of Physicians, which appointed a special Committee to investigate the subject. The Committee reported that "after careful scrutiny of the statistics from both official and private sources which have been made available, we are of opinion that not only is a lessened susceptibility to the disease brought about as a result of the inoculations, but the case mortality is largely reduced." The Committee went on to say: "We are further of opinion that with due care the process of inoculation is devoid of direct danger, but that under special circumstances there may possibly be some temporary increase of susceptibility to infection immediately following inoculation; and it is, therefore, desirable that the preparation of the vaccine and the inoculations should be carried out under specially skilled supervision." This report, however, failed to convince the Advisory Board that its decision against the inoculations had been mistaken. Dr. Wright, on his part, persisted in his efforts to vindicate the reputation of his serum, and a few months ago another Committee of Inquiry was appoined by the War Office. The members of that committee were Dr. C. J. Martin, Director of the Lister Institute of Preventive Medicine; Dr. A. Macfadyean of the same Institute; Dr. Caiger, an acknowledged authority on fevers; Dr. Bruce Low, an Inspector of the Local Government Board; Dr. Bulloch, bacteriologist to the London Hospital; Colonel David Bruce, of the Royal Army Medical Corps, whose name is associated with researches on Malta Fever and Sleeping Sickness; Dr. Galloway, physician to Charing Cross Hospital; Dr. Wright himself and Major Leishman, his successor in the Chair of Pathology at Netley. Colonel Bruce and Dr. Galloway are members of the Advisory Board above referred to, and the former is said to have been an active opponent of the inoculations. This committee reported that "the antityphoid inoculation had resulted in a substantial diminution in the incidence and case mortality from typhoid fever, and recommended that the system introduced by Professor Wright should be resumed in the Army." This recommendation has been adopted by the Army Council, and a commencement is about to be made by inoculating volunteers from a regiment under orders for India. Wright, therefore, would seem to have triumphed over his enemies. Nevertheless, he is not satisfied, and he and his *fidus Achates*, Bulloch, have shaken the dust of the committee-room off their feet, because the carrying out of the inoculations has been entrusted to Major Leishman, who will be assisted by medical officers of the Army. The reason given is that the process is not yet perfect, and its further improvement require the labor of years, and the work can be done properly only by a permanent committee consisting of civilian experts and army medical officers. Which, being interpreted, means that Wright thinks that the task should have been entrusted to himself. It is only natural that he should think so, as the invention is his and he has so far worked without reward or recognition of any kind from the Government. It may, however, be said of him, as Carlyle's mother said of that prophet of pessimism, that he is "gey ill to deal wi'." He attributes the transference of the management of the inoculations to Leishman to the malign influence of Bruce. This may very well be true, but it is not the whole truth. Moreover, Wright is scarcely entitled to sympathy as a victim of personal hostility, as in his capacity of member of the Indian Commission on Plague, he took an attitude of such opposition to Haffkine, the inventor of a protective serum against cholera, that in the eyes of many the conclusions of the Commission were so vitiated thereby as to be of no real value. He has appealed to the press, and the *Times* of October 27, in an evidently inspired article, has put his case before the public in such a way as to give the impression that he is a martyr of science. This no one who knows him will be disposed to believe. It is quite true that he appears to have been badly treated, but he has a talent for making enemies. Those who know to what an extent such personal jealousies warp the judgments of men whose sole object is supposed to be the discovery of truth may be pardoned if they hold the decisions of scientific commissions just as liable to error as theological councils, and as much subject to the disturbing influence of human passion as political parties.

The Royal Colleges of Physicians and Surgeons have decided to give up the preparation of antidiphtheria serum. The work is, however, to be taken up by the Metropolitan Asylums Board for one year as an experiment. It will be carried on in the same laboratories and with the help of the same scientific staff as heretofore. The Colleges have for some years past issued from 20,000 to 30,000 doses of antitoxin of 3,000 units each, most of which has been used in the hospitals of the Metropolitan Asylums Board. In 1894 the Colleges undertook the bacteriological examination of diphtheria cases in these hospitals. The object was that the treatment might be tested on a large scale. At that time the serum was regarded with considerable doubt not only by the public but by not a few members of the medical profession, and it was believed that if the serum were prepared with the sanction of the Royal Colleges more confidence would be felt in the remedy. The Colleges have no profit out of the work, and their abandonment of it may be taken as evidence that the purpose which they had in view has been fulfilled. Henceforward the serum will not have the guarantee of the Colleges, and the Metropolitan Asylums Board is not in a position to supply anything of the kind in its place. Moreover, if the Board decides to discontinue the manufacture at the end of the year of trial, what is to happen? The preparation of the serum will be left to private enterprise, and as such will be open to the suspicion of commercialism from which it has hitherto been free in this country.

Mme. Curie. The co-discover with her husband is a comparatively young woman. She was born in Warsaw in 1868. Her father, being an excellent naturalist, encouraged her taste for mathematics and she obtained her degree in that branch at Paris in 1891. Here she met Professor Curie and they were married. Together they have enriched the subjects of physics and chemistry to a remarkable degree.

SOCIETY PROCEEDINGS.

SOCIETY OF THE ALUMNI OF CITY HOSPITAL.

116th Stated Meeting, held October 12, 1904.

Malignant Growth of the Penis.—Dr. Reynolds presented two cases which exhibited a probable malignant growth of the penis. He showed a very graphic oil painting of one of the lesions. In both cases the patients were just over forty years of age, and in each the organ was satisfactorily removed.

Operation for Hemorrhoids.—Dr. Lyle reported a case in which after a simple routine operation for hemorrhoids there had been persistent failures to heal. Four months after the operation Dr. James Tuttle was called in consultation. He said at once that he had recently seen three or four similar cases and before he had examined the patient, he stated that it was probably tuberculous or syphilitic. Pathological report showed it to be the latter.

Appendectomy.—Dr. Lyle reported a case of appendectomy in a woman sixty-five years of age. In less than twenty-four hours after the advent of the first symptom, the abdominal cavity was found full of pus. The symptoms were of an insidious character. The point he emphasized about this case was that through drainage was established through Douglas's sac. A gauze drain passing continuously from the abdominal wound through the vagina. It was in situ for three days and was then removed from below. He considers vaginal drainage of very great importance.

Difficulties in Anesthetization and Their Correction.—Dr. Victor C. Pedersen read this paper. The text of this paper will be found in a subsequent issue of the MEDICAL NEWS.

Dr. J. T. Gwathmey, in opening the discussion on Dr. Pedersen's paper, said that among the many minor points in connection with anesthesia, none seemed to him more important than the fact that in the first and second stages of nitrous oxide anesthesia, the patient can hear and appreciate many of his surroundings. Since the mental condition has unquestionably much to do with the physical post-operative well-being, great care should be taken during these two periods that nothing is said or done to alarm the patient. Another minor consideration is to be found in executing the change from the gas to the ether. As is well known, rigidity often manifests itself at this period, and here perhaps more than anywhere else in the course of the anesthesia, rigidity means deficiency of air. He agreed with Dr. Pedersen that a tracheotomy set should always be a part of the anesthetist's outfit.

As for chloroform as an anesthetic for tonsil and adenoid operations, he would, if left to himself, invariably choose ether, the acceleration of respiration from this admirable stimulant being highly advantageous. He felt that less hesitation should be shown in changing a refractory patient from chloroform to ether or vice versa, than many anesthetists were wont to show. Attention to the purely respiratory conditions of the patient often sufficed to keep the anesthetist busy, and a nurse should be employed to watch the pulse. He invariably gives a bagful of gas with or without oxygen for the last fifteen minutes of an operation, believing, not only that the patient thereby receives less ether, but is enabled to come out of the anesthetic very much more rapidly than is otherwise the case. For vomiting he has found that a substitution of the ether-soaked towels for bowels saturated with cologne, amyl nitrite and spirits of ammonia is often highly efficacious. He closed by saying that he believed that the utmost care should be taken in removing patients from the operating room to their beds.

Dr. Nathan W. Green said, that it was an undoubted fact that, just as in local anesthesia, a patient likes to grasp something very tight in the hands, so in major anesthesia ability to grasp some object is comforting and quieting to the patient. He therefore always reassures and quiets him by having him hold the hands of an attendant very tightly. He further believes that advising the patient that he will, when the mask is put over his face, get nothing but abundance of pure fresh air, is distinctly advantageous. The gas can then be turned on by a quick and noiseless movement almost without the patient's knowing it. Gas anesthesia should not be carried too far, since it predisposes to vomiting in the early stages of ether anesthesia. He believes that a suture through the tongue to hold it in the rare cases in which it cannot otherwise be supported is better than any form of tongue forceps. It is a mistake, in the opinion of the speaker, always to crowd the ether, if a patient is vomiting, for as already suggested such vomiting may be due to other causes, one of which is too profound gas anesthetization. He called the attention of the society to the well-known experiment upon the reptilian heart in which the organ is poisoned by muscarine until it stops beating and is then brought back to normal activity by having a few drops of an atropine solution poured upon it. This should be remembered as indicating the value of atropine in threatened death from circulatory stagnation during anesthesia. Dr. Green believes it to be of very great convenience to have the gas remain connected with the anesthetic apparatus throughout the operation. In his opinion it should not be disconnected at all, but should remain on tap at any moment, for it is the most ready and convenient way to overcome the very inconvenient returns to semi-consciousness, which are by no means uncommon when patients are being kept very lightly under the anesthetic. He is a thorough advocate of the closed method, but as some surgeons insist upon the use of open methods and inasmuch as this seems to work better in a very few cases of alcoholic patients, it is well to have an old-fashioned towel cone at hand.

Dr. Wiesner spoke of the old days of anesthesia and how completely the ancient methods have gone out of use. He expressed his thanks and that of the Society to the experts who had spoken so interestingly on this important subject.

Dr. Waterman believed that the anesthetist in these days of specialization must know more than the operating surgeon about the anesthetic and should be given his choice of what to use.

Dr. Terriberry took issue with this view on the ground that the anesthetist, as an entire stranger and ignorant of the pathological conditions, could not possibly be as good a judge of the type of anesthetic indicated as the operator. It seemed to him that a consultation between the two would give better results.

Dr. Hough spoke of the importance of counting, especially in children. It is a most serviceable way to divert their attention and to save them from panic. He said that atropine should be used judiciously, especially in elderly people, for several cases of glaucoma had resulted from the use of it.

Dr. Pedersen, in closing, said there never was any question in his mind as to the correctness of the belief that when most patients stiffened out, they needed an abundant and free supply of air. He believed that a failure on the part of the operators while removing adenoids and tonsils, to put the patient into Rose's position was responsible for immediate and remote complications much more definitely than the use of chloroform in place of ether. In giving chloroform he considers it essential to administer it drop by drop rather than as is commonly done by intermittent floodings. He agreed with Dr. Green that the patient should be told that a period of suffocation will probably come. If they are prepared for this, they will not mind it. Masseteric rigidity can be conveniently handled by placing a pair of rubber-covered forceps back of the jaw and opening the mouth. This gives the anesthetist both hands free. He disagreed with Dr. Green, however, very vehemently as to the possible indications for the use of the old-fashioned cone. He believes that none exists. As usually made, this cone is a stumpy affair more than half filled with cotton and towels for the reception of the ether. If under any conditions such a shape of cone should be used, it ought to be made at least a foot high so that there shall be an air space of 500 c.c. This represents the average tidal air and is necessary both for safety and for comfort. Dr. Pedersen cited a case which seemed to him to offer positive proof that anybody could be put out with the metal cone without a struggle.

JOHNS HOPKINS HOSPITAL MEDICAL SOCIETY.

Stated Meeting, held October 17, 1904.

Dr. Joseph C. Bloodgood was elected president and Dr. C. H. Bunting secretary for the ensuing year.

Plastic Operation on the Face.—Dr. Stephen Watts exhibited a patient on whom a plastic operation had been done for a wound of the lower lip and chin. The boy, fifteen years old, had been bitten by a circus-pony, and the soft parts, from the mouth down, removed, including the periosteum. The wound was a clean one. A flap was dissected from the upper arm, its under-surface and the raw area left by it being covered by a graft taken from the thigh. After sufficient time had elapsed for the establishment of circulation in the flap it was sutured to the face wound, its pedicle being still left attached to the arm, which was bound up to the chin by a plaster dressing. At the end of three weeks the flap was gradually separated from the arm, the operation being done in several sittings. Photographs of the patient before, during and after the treatment were exhibted, showing the change from a terrible deformity to a fairly normal appearance.

Metastatic-melanosarcoma and Adenocarcinoma of the Umbilicus.—Dr. Cullen reported three gynecological cases: The first, a woman of fifty-eight years, complained of abdominal enlargement, pigmentation and loss of weight, for which no cause could be discovered. There was a small mole on the neck. The abdomen was opened and an umbilicated new growth of the liver and omentum found, which proved to be a melanosarcoma with areas of pigmentation. Metastasis from the mole in the neck seemed probable. The second case, a woman of forty-two years, had been struck on the abdomen, and after three weeks had begun to have a discharge from the umbilicus, around which there was a collar of induration. The inguinal glands became enlarged. The involved area about the umbilicus was excised, and the omentum and glands of the groin removed. The tissue proved to be adenocarcinomatous, and the probable primary site was the umbilicus. The third case was one of a patient who had had a carcinomatous kidney removed one year ago. After seventeen months of health a tumor was noticed developing in the right side, which rapidly increased in size, caused loss of weight, and was accompanied, on admission, by a temperature of 102.5° F. On opening the abdomen the tumor was seen bulging under the liver. It was removed with a knife, after clamping the cystic duct, a suture being placed with a dull needle as the cut was made. The tumor proved to be a metastasis from the carcinomatous kidney. The patient convalesced without event and was discharged four and one-half weeks after operation. Macroscopically there was apparently little liver destruction. Round, blunt, knife-blade needles were used in this case, following the suggestion of an assistant of Mikulicz, who showed that with proper needles the liver could be sutured almost with impunity, all vessels being pushed aside and no bleeding occurring from the stitch hole.

Dr. Futcher, in the discussion, referred to Dr. Keen's paper on the importance of pigmented moles, and reported a case of a colored man with a mole on the right scapula whose axillary glands showed melanotic sarcoma.
